The Lymphocyte and Human Lung Cancers

SUMMARY

With an autologous tissue culture system, a quantitative determination has been made of random and special lymphocyte interactions with neoplastic and nonneoplastic cells derived from 68 surgically resected human lung cancers. Random activities consist of lymphocyte movements among neoplastic and nonneoplastic cells, whereas special activities (clustering, congregation, emperipolesis) involve attachments of three or more lymphocytes to other cells or penetration into a cell. The frequencies of the interactions and the ratios of special-to-random interactions were determined for nonneoplastic epithelial, spindle, and histiocytic cells and for neoplastic cells. Cancer cells showed the lowest levels of overall lymphocyte interactions and were characterized by high ratios of special-to-random interactions, with epidermoid cancer as an exception in the latter respect. High ratios were also found for nonneoplastic cells derived from cancer-bearing explants, whereas the ratios for cancer-free counterparts were consistently low. The nonneoplastic epithelial cell was the outstanding example of the reversal in ratios. These findings support the concept that a defective lymphocyte-cancer cell interaction occurs in neoplasia and also indicate that cancer tissue influences the in vitro response of lymphocytes to nonneoplastic cells. These new measurements of autochthonous and distinctive lymphocyte-cancer cell interactions with neoplastic and nonneoplastic cells are of potential value for the evaluation of host response and cancer tissue uniqueness in a given patient.

INTRODUCTION

Lymphocytes unquestionably play an important role in host resistance to cancer (3–6, 19), but there is remarkably little information about lymphocyte-cancer cell interactions, especially with respect to what kinds of interactions occur, the frequency of each type of interaction, their functional significance, and how they may be evaluated. This is particularly true for human lymphocyte-cancer cell interactions, and in this respect a new approach has recently been proposed (23, 27) that appears to offer an opportunity to extend our knowledge about such interactions substantially beyond that afforded by other presently used methods. In essence, the method uses primary explants of human cancers in autologous and short-term tissue culture systems and permits several useful measurements of distinctive types of lymphocyte activities. In particular, the presence or absence of different types of lymphocyte activities in "colonies" (to be defined) of neoplastic and nonneoplastic cells appears to be not only a valid means of establishing in part the degree of lymphocyte response but also seems to reflect special functional capabilities of the lymphocyte. Moreover, both colony counts and ratio determinations, i.e., frequencies of each type of lymphocyte interaction in a given cell population, the number of lymphocytes participating in each interaction, and the types of target cells involved, can be achieved with biopsy samples of cancer tissues. Thus, this new approach has the potential to bypass much of the sampling and evaluation problems of the histological preparation.

Although there are a number of recent publications on lymphocyte interactions with neoplastic and nonneoplastic cells in vitro (10, 11, 15, 21, 22, 25, 28, 32, 33, 41–43), there are few reports wherein lymphocyte interactions with human cancer cells have been studied in an autologous tissue culture system (2, 7, 8, 16). Most pertinent, there have been no studies except for our own preliminary reports (24, 26, 27) specifically designed to evaluate intrinsic autologous lymphocyte-cancer cell interactions, i.e., where lymphocytes are already a part of the cancer mass and are not secondarily introduced. Further, the evaluation includes 1 random and 3 special types of lymphocyte activities [clustering (31), congregation (24), and emperipolesis (16)] occurring among human neoplastic and nonneoplastic cells in primary tissue cultures.

The emigrating lymphocytes in primary tissue cultures of lung are classified as migratory and ameboid lymphocytes because of their differences in appearance and behavior (24). The migratory lymphocytes are rounded or pear-shaped cells, while the ameboid lymphocytes are cells with remarkably "spread" cytoplasm and nucleus, the spreading indicating an extraordinary increase in surface area contact with other cells. The lymphocyte interactions with neoplastic and nonneoplastic lung cells are divided into "random" and 3 "special" types of interactions, determined through phase-contrast observations, time-lapse film reviews, and examination of stained preparations. Both migratory and ameboid lymphocytes participate in random interactions with neoplastic and nonneoplastic cells; on occasion, 1 or 2 lymphocytes may localize briefly on a cell of the monolayer, but penetration of the cells by the lymphocyte does not occur

Lymphocytes and Cancer

Phase-contrast microscopy was used for daily observation of the Rose chamber cultures.

The cells emigrating from the cancerous and "normal" lung explants were identified by a correlative methodology that included whole-lung thin sections (14), routine histological preparations, phase-contrast microscopy, May-Grunwald-Giemsa-stained monolayers, and time-lapse filming. Criteria for the special type of lymphocyte activities and the identification of cancer cells have been previously described (24, 37).

In brief, identification of cancer cells is based on a recently recognized tissue or organoid form of in vitro cancer (37). In essence, identification begins with in vitro cancer tissue, which is the equivalent of an unstained, but living, histological preparation. Architectural integrity is preserved, e.g., the cell-to-cell relationship of epidermoid cancer is presented as a "whorl" with a typical epithelial "pearl" (36, 37). The emigration and spreading of cancer cells from the organoid form of the cancer leads to monolayer formation (Fig. 5). Identification of the cancer monolayers is achieved through the finding of areas transitional between the monolayer and tissue forms and through continuous time-lapse filming of the emigration. Also, a number of nuclear and cytoplasmic characteristics of the in vitro cancer tissue persist in the monolayer.

Nonneoplastic epithelial cells originating from ciliated epithelium, a common component of cultures derived from normal lung parenchyma, were readily recognized by the persistence of cilia during the early period of monolayer outgrowth. The cytostructure, staining properties, and growth patterns of these cells readily distinguished them from the other 2 nonneoplastic cell categories, i.e., spindle cells and macrophages. Other nonneoplastic epithelial cells, presumably derived from the mucosal and alveolar linings, shared a number of properties with those of ciliated cell origin and conformed to the pattern of growth commonly observed in tissue culture preparations of CF lung parenchyma. Thus, the characteristics of the parenchymal epithelial cells and the positive identification of the cancer cells as described served to distinguish nonneoplastic from neoplastic epithelial cells.

All fusiform cells with the characteristics of connective tissue monolayers were classified as spindle cells, and cells placed in the macrophage category were characterized by individual cell movements, distinctive membrane patterns, phagocytic activity, and staining properties. In regard to lymphocytes, no distinction was made as to size or organ of origin. All of the nonneoplastic cells were derived from 2 major sources, normal lung parenchyma from a CB lung and lung parenchyma within the cancer tissue itself, i.e., the bronchioloalveolar and other structures that persist despite cancerous invasion and destruction.

In this study, a cell colony was defined as either an outgrowth or an isolated group of 100 or more cells of a single type. Three neoplastic and 3 nonneoplastic cell types were studied; namely, epidermoid cancer, adenocarcinoma, and undifferentiated carcinoma on one hand and nonneoplastic epithelial cells, spindle cells, and macrophages on the other. The colonies were observed for the presence or absence of special and random lymphocyte interactions, and they were

MATERIALS AND METHODS

CB and CF tissues derived from 68 surgically resected human lungs were studied in tissue culture. A small wedge of the tumor periphery was removed under aseptic conditions, and the most vailable-apparing portion was selected for explantation. In addition, a small piece of grossly normal lung parenchyma (distant from the cancer) was explanted in 25 of 68 cancerous lungs. The tissues selected were washed and maintained in Eagle's (12) double-strength amino acid medium supplemented with 20% calf serum, 5% bovine embryo extract ultraltrate, 100 units/ml penicillin, 100 μg/ml streptomycin, 500 mg/100 ml glucose, 25 mg/ml L-glutamine, and phenol red indicator (0.005% final concentration). Details of the tissue culture procedures have been reported previously (24).

In brief, 60 approximately 1- x 2-mm fragments of cancer tissue were set up from each cancer, and 30 fragments were set up from each portion of nonneoplastic lung tissue. Rose chambers with unperforated cellophane strips (29, 30) and Leighton tubes (17) containing glass coverslips were used throughout the studies. The quantitative determination was restricted to the Leighton tube cultures, which were sacrificed by methanol fixation at specific intervals. Histological processing of the explants and May-Grunwald-Giemsa staining of the culture outgrowth were carried out at 4, 24, 48, and 96 hr; 7 days; and weekly thereafter, up to 6 weeks.

The abbreviations used are: SI, special interaction; CB, cancer bearing; CF, cancer free; TCI, total combined interactions; RI, random interaction.
RESULTS

Of 68 lung cancers explanted in vitro, 48 (71%) yielded cancer cell outgrowth in Leighton tube preparations. However, cancer tissue was demonstrated in all histological preparations of the explants following sacrifice after varying periods of in vitro life. In respect to lymphocyte emigration from the explant, an 82% yield was obtained when the findings of both Leighton tubes and Rose chambers were combined. The Rose chamber was advantageous for this purpose since the cellophane strip in the chamber retains lymphocytes within the immediate vicinity of the explant, a feature particularly helpful when only a small number of lymphocytes emerge and when the medium is changed. The 56 lung cancers with preparations positive for emigrating lymphocytes included 18 adenocarcinomas (50% of total adenocarcinomas), 20 undifferentiated cancers (69% of total undifferentiated cancers), and 21 epidermoid carcinomas (90% of total epidermoid carcinomas). In respect to the number of lymphocytes emerging from the various explants, there was a range of a few per low-power field to a densely populated band 2.0- to 3.0-mm thick, with the maximal number of lymphocytes found during the 2nd day of in vitro life. Most of the lymphocytes emerging during the 1st few days of in vitro life were of the “migratory” type, i.e., pleomorphic, freely moving, and refractile (phase-contrast microscopy) cells. As other cells emerged from the explants, some of the migratory lymphocytes spread on their surfaces to become ameboid lymphocytes (24), thus not only appearing to be much larger than the migratory form but exhibiting clearly visible nuclei, delicate cytoplasmic membranes, and well-defined cytoplasmic organelles.

In respect to the interactions of lymphocytes in colonies of neoplastic and nonneoplastic cells, there were several outstanding findings (Chart 1). (a) In reference to the TCI, i.e., a percentile tabulation that combines SI and RI of lymphocytes, the cancer cell colonies show a much lower level of response than the migratory lymphocytes emerging during the 1st few days of in vitro life were of the “migratory” type, i.e., pleomorphic, freely moving, and refractile (phase-contrast microscopy) cells. As other cells emerged from the explants, some of the migratory lymphocytes spread on their surfaces to become ameboid lymphocytes (24), thus not only appearing to be much larger than the migratory form but exhibiting clearly visible nuclei, delicate cytoplasmic membranes, and well-defined cytoplasmic organelles.

against time of in vitro life (Charts 3 to 6), there is a trend for most interactions to peak at 7 to 14 days. By the 28th day of in vitro life, there were few instances of SI or RI, but isolated examples of each could be found in cultures as old as 100 days.

The ultimate fate of the cells involved in SI was observed in relatively few instances, but it was evident that in some cases 1 or both of the interacting cells, the lymphocytes or the target cell, underwent degenerative change.

**DISCUSSION**

It appears that short-term cultures of human cancers can provide data on lymphocyte-cancer cell interactions, which are in some way a reflection of “host resistance.” Although clinical correlation of the data obtained in this study must await long-term follow-up, some of the findings tend to parallel and supplement the histological indicators of prognosis (3, 38). Of more immediate importance, the methodology has a number of attributes that strongly support its future usefulness. (a) The exclusively autologous cell populations studied and the short-term observation periods (beginning immediately after explantation and rarely extending beyond 6 weeks) assure preparations that are more representative of the in vivo state than the more commonly used tissue culture methods, i.e., cell lines, cell strains, artificially constructed mixed cell populations, and heterologous systems. (b) The appearances and interactions of cell populations derived from...
A. Richters, R. P. Sherwin, and V. Richters

Some other factors involved in the interaction. The nonneoplastic epithelial cells, which are in a sense benign counterparts of the cancer cells, show a response parallel to the cancer cells in the situation where they are derived from CB explants. The fact that this is not the case for those derived from CF explants tends to imply that a defective lymphocyte interaction exists with cancer-associated epithelial cells as well and is a reflection of the cancerous process, i.e., epithelial cells in the vicinity of the cancer are in some way either influenced by or are a part of the neoplastic process, the latter idea being in line with the concept of a "field effect." (39).

A very intriguing aspect of the data is the fact that cancer cells and nonneoplastic cells in the vicinity of cancer tissue are dominated by special, not random, types of lymphocyte interactions. Some of these SI have already been linked in part to lymphocyte-cancer cell responses. Lymphocyte clustering, for example, can be produced experimentally by sensitizing lymphocytes to a specific cancer (1) or, for that matter, to a number of nonneoplastic cells. Emperipolesis has been shown in this study to be the predominant, almost exclusive, CB as opposed to CF tissue of the same lung can be compared under essentially identical environmental conditions. (c) A number of lymphocyte properties can be detected and measured as part of a host defense evaluation, including viability, longevity, special structural forms and transitions, special forms of behavior, and responses to selected challenges or special environmental conditions.

Insofar as prognostic considerations are concerned, it is noteworthy that, of all the lymphocyte interactions, i.e., with epithelial cells, spindle cells, macrophages, and cancer cells, those involving cancer cells were the least frequent (Chart 1). This is consistent with our earlier observations (34) and the hypotheses of others (9) that a defective lymphocyte-cancer cell interrelationship exists. However, there is little insight at the present time as to whether the defect is mainly of the lymphocyte, the cancer cell, a combination of the 2, or of
interaction of lymphocytes with cancer cells. This is in accord with the study of Humble et al. (16), who concluded that "the lymphocyte has a remarkable affinity for malignant cells." However, as our report points out, the affinity of lymphocytes for lung cancer cells is essentially restricted to this interaction, whereas the overall interactions are clearly diminished. With respect to emperipolesis in nonneoplastic cells, a possible link to atypism and perhaps precancerous change is also suggested by the findings. Particularly significant is the fact that nonneoplastic epithelial cells derived from CB explants were found to exhibit an almost 4-fold greater frequency of emperipolesis than do the corresponding cells from CF explants (Chart 2). Far less significant differences in this respect were noted for spindle cells and macrophages. Emperipolesis was much less frequent for epidermoid cancer than for undifferentiated carcinoma and adenocarcinoma (Table 1), a finding that may have "host-status" meaning, considering the generally more favorable prognosis for epidermoid cancer of the lung. At the same time, it should be noted that random interactions for epidermoid carcinoma are twice as frequent as emperipolesis, whereas for the other 2 cancers there is an outstanding reversal. The latter findings emphasize the value of subdividing lymphocyte interactions, inasmuch as the overall total interactions showed relatively little difference.

The specific mechanisms involved in the various lymphocyte interactions and the functional meaning of the interactions are to date essentially unexplained. Emperipolesis is a remarkable phenomenon, but little can be said about its meaning other than that it may be an extraordinary means of internal surveillance of the cell. There is a speculative opinion that the ameboid form of the lymphocyte may represent a "conditioning" response (24), but neither this activity nor the related phenomenon of congregation have been linked in any way to cancer, other than the implications of this study. Congregation has also been reported for macrophages, and the phenomenon has been related to certain in vitro cells derived from the lungs of guinea pigs exposed to nitrogen dioxide (35).

An obvious aspect of all of the SI is the intimate contact of the lymphocyte to the target cell, either in the form of "foot appendages" (18) (migratory lymphocyte) or extended cell surface area [ameboid lymphocyte (24)]. Therefore, it is likely that alterations at the cell surfaces, especially electrostatic disturbances (9, 13), or the presence of an antibody coat (15) may be responsible for prevention of intimate cell contacts by the lymphocyte. Thus, it is possible for a large number of lymphocytes to be near cancer cells and yet not be effective. The seemingly paradoxical situation where emperipolesis is increased under these circumstances may possibly be explained on the basis of lymphocyte-host cell antagonism, the lymphocytes penetrating into the cell but becoming trapped inside it. That trapping is an actual event is supported by the fact that lymphocytes within lung cancer cells often die, producing inclusion bodies (Fig. 9), and that "near entrapment" of lymphocytes in nonneoplastic cells has been observed via time-lapse films. It is also possible that the lymphocytes are functionally defective although able to penetrate cancer cells, an aspect supported by the fact that delayed or otherwise impaired homograft rejection phenomena are often found in cancer patients (40). Further, lymphocyte populations are heterogeneous, and it may be, as Mikulsk et al. (20) have suggested, that cancer states are associated with decreased numbers of "antitumor" lymphocytes.

There is a great need for information about the relationship of each patient's clinical course to lymphocyte-cancer cell interactions, and in this respect this study represents a beginning. The primary short-term cultures, the documented cancer cells in vitro, the quantitative approach to evaluation of lymphocyte-cancer cell interactions, and the attention to unique lymphocyte activities can provide, with refinement and amplification, a means of obtaining needed insight into the problem of human host resistance to cancer.
