ABSTRACT

Sensitivity to ultraviolet radiation was studied in lymphoblastoid cell lines derived from 32 members of two families with histories of multiple primary melanomas in several generations. As assayed by colony formation in agar or by trypan blue exclusion following irradiation, cellular sensitivity showed a bimodal distribution. All persons with melanoma or multiple moles were in the sensitive group, while some family members exhibited responses similar to those of controls. Cells from four cases of sporadic melanoma showed normal levels of sensitivity. The data are consistent with a dominantly inherited ultraviolet light sensitivity associated with these examples of familial melanoma.

Spontaneous and ultraviolet light-induced sister chromatid exchange frequencies were similar to those in control cell lines. No defect in excision repair was detected in any of the above cell lines, but the sensitive group showed postirradiation inhibition of DNA replication intermediate between controls and an excision-deficient xeroderma pigmentosum cell line.

INTRODUCTION

The accumulated evidence from studies on XP in the past decade (20) demonstrates that autosomal recessive mutations can be important determinants of some cases of malignant melanoma in humans. Evidently, homozygosity is required, since epidemiological evidence suggests that XP heterozygotes are not at increased risk of developing melanomas (22). While the majority of melanomas are sporadic, a proportion occur in successive generations of a family. A population-based study in Australia (25) estimated that first-degree relatives of melanoma patients were 1.7 times more likely to develop melanoma than were persons in the general population. In this study, it was estimated that 11% of malignant melanoma in that population was of genetic origin. It has been pointed out that the latter figure is likely to be an underestimate because of the high UV exposure in the population studied, which would be expected to increase the rate of sporadic cases (10). However, in general, some of the patterns observed do not necessarily exclude familial clustering on the basis of common environmental exposure.

Delineation of genetic and environmental factors is important both in the elucidation of the etiopathogenesis of this class of malignant tumor and for prognosis of individuals within families in which melanoma occurs. The description of the B-K mole or dysplastic nevus syndrome involving hereditable melanocytic lesions which predispose to familial malignant melanomas (4) has been an important contribution to the definition of genetic factors predisposing to melanoma. We report here laboratory data, from studies on 2 large unrelated pedigrees with multiple cases of malignant melanoma, which are consistent with a dominant mutation giving rise to UV radiation sensitivity in association with a liability to develop cutaneous malignant melanoma.

MATERIALS AND METHODS

Cells. Peripheral blood lymphocytes were isolated (16) from 12 members of Family A (designated in the series FM201ABR-FM214ABR) and 20 members of Family B (designated in the series FM101ABR-FM136ABR). Family A members were of Celtic origin, living in a district about 100 miles southwest of Brisbane. There were 6 known cases of cutaneous malignant melanoma among 13 individuals in 2 generations (generations I and II). Some individuals also had basal cell carcinomas and/or moles. Five members in generation II and 7 of their children (generation III) were available for study. Family B members were also of Celtic origin, living in or near Perth in Western Australia and unrelated to Family A. Fourteen cases of cutaneous malignant melanoma were recorded among 30 members in 3 generations (generations I, II, and III). Some members had dysplastic nevi, but neither family conformed in all respects to the B-K mole syndrome. Lymphocytes were also isolated from 4 sporadic cases of melanoma (cell lines 371LABR, 373LABR, 376LABR, and 377LABR) with no family history of the disease. Nine control samples (designated in the series C1ABR-C11ABR) were collected from individuals with no personal or family history of melanoma or other skin cancer, and one XP cell line (XP301ABR) was established from a patient with neurological abnormalities (Complementation Group A). Lymphocytes were transformed with Epstein-Barr virus to produce lymphoblastoid cell lines (15). An XP variant (GM2449) cell line was obtained from the Human Genetic Mutant Repository, Camden, N. J. Cells were grown in RPMI 1640 (Microbiological Associates, Walkersville, Md.) medium supplemented with 10% fetal calf serum at 37° in 5% CO2.

UV Irradiation. Cells were washed and suspended in PBS. A thin film of the cell suspension of up to 10^6 cells/ml was added to a 35-mm bacterial plate and irradiated with a UV lamp (Mineralite UVS 12; Ultraviolet Products, Inc., San Gabriel, Calif.), at a dose rate of 0.5 J/sq m/sec. The incident dose of UV was measured with a UV intensity meter (Ultraviolet Products, Inc.), or by malachite green spectrophotometry (9). Medium was returned to cultures immediately after irradiation.

Determination of UV Sensitivity. Cell survival after UV irradiation was determined by colony formation in agar (2). The viability of lymphoblastoid cells at various times after UV irradiation (15 J/sq m) was determined by trypan blue (Gurr Hopkins and Williams, Essex, England) exclusion (2).

DNA Repair Synthesis. Lymphoblastoid cells growing exponentially at a density of 5 x 10^6/ml were incubated with 20 mm hydroxyurea...
(Sigma Chemical Co., St. Louis, Mo.) for 30 min prior to irradiation to ensure a 99% reduction in DNA replication. At this concentration of hydroxyurea for this time period in these lymphoblastoid cells, it was possible to discriminate clearly repair in control versus XP cells. Cells were collected by centrifugation and resuspended in PBS. Following irradiation with UV (40 J/sq m), DNA repair synthesis was measured in the presence of 20 mM hydroxyurea and [3H]thy midine (5 μCi/ml; 46 Ci/mmol; The Radiochemical Centre, Amersham, England) during a 2-hr incubation at 37°. Incubation was stopped by harvesting cells on GFC paper discs with the aid of a Dynatech Multimash Harvester. Discs were dried and treated with Soluene 350 (Packard Instrument Co., Downers Grove, Ill.), scintillant was added, and radioactivity was assayed in a Packard Tri-Carb scintillation counter.

**DNA Replication after UV irradiation.** The rates of DNA synthesis were determined in lymphoblastoid cell lines after UV irradiation (8). Cell densities were adjusted to 2 × 10^6 cells/ml, and cells were prelabeled for 18 to 24 hr with [3H]thymidine (0.01 μCi/ml; 57.7 mCi/mmol; The Radiochemical Centre).

Cells were washed and resuspended in PBS for irradiation with UV (5 J/sq m). Controls were treated similarly but were not irradiated. Cells were resuspended in warm medium and incubated at 37°. At various times during the postirradiation period, aliquots of cells were pulse-labeled with [3H]thymidine (10 μCi/ml) for 15 min. Samples were processed as described above, and the [3H]:[14C] ratios in the UV-irradiated samples were compared with those in the unirradiated samples taken at that time point.

The rate of chain elongation following UV was determined on alkaline sucrose gradients (12). Cells were pulse-labeled with [3H]thymidine (50 μCi/ml) for 60 min and chased for 75 or 150 min in the presence of 10 μM thymidine and 10 μM deoxyctydine (Sigma). Reactions were terminated by freezing on dry ice.

**Unscheduled DNA Synthesis.** Cells were washed and irradiated as described previously with UV (20 J/sq m). Cells were returned to warm medium and incubated for 4 hr in the presence of [3H]thy midine (10 μCi/ml). Cells were washed and incubated for 30 min in the absence of radiolabel and then washed and fixed in methanol/glacial acetic acid (3:1).

Following several washes in fresh fixative, slides were prepared for autoradiography as described previously (18). At least 250 non-S-phase cells were scored for each irradiated cell line. Background counts were determined on unirradiated cells by counting grains over non-S-phase cells for each cell line.

**SCF.** Lymphoblastoid cells were irradiated with UV (2 or 4 J/sq m) and immediately transferred in subcultured into medium with 10 μM BrdUrd (Sigma) (24). Cells were incubated in the dark for 46 hr and then with Colcemid (0.2 μg/ml; Grand Island Biological Co., Grand Island, N. Y.) for 2 hr. Cells were fixed, washed twice, and left overnight.

Freshly prepared slides (using fresh fixative) were air dried, layered with Hoechst 33258 stain (50 μg/ml; Aldrich Chemical Co., Milwaukee, Wis.) in distilled water (pH 7.0), and then irradiated with black light for 2 hr. The slides were rinsed in distilled water, incubated at 65° for 15 to 30 min in 0.3 M sodium chloride:0.03 M trisodium citrate, and then cooled and stained with Giemsa (Gurr, Hopkin and Williams) in phosphate buffer (pH 6.8) (24). Twenty-five or more metaphase cells were scored for each treatment.

**RESULTS**

**UV Sensitivity.** Lymphoblastoid cell lines have been shown to reflect UV sensitivity exhibited by fibroblasts in the case of XP (1) and ionizing radiation sensitivity in the case of ataxia telangiectasia (2). In the present experiment, irradiated lymphoblastoid cells showed a bimodal distribution of radiosensitivity in both families. Data obtained by assay of prolonged viability by trypsin blue exclusion for cell lines listed from Family A (not shown) were consistent with data obtained with the same cell lines assayed by colony formation in agar (Chart 1). Both methods indicated that there was an abnormally UV-sensitive group (Group S) and a normally sensitive group (Group N).

In view of the identical subgroup classification of all individuals in Family A by both methods, cell lines from Family B and 4 sporadic melanoma patients were assayed for UV sensitivity by the preferred method of colony formation only. Chart 2 shows the distribution of D0 values obtained in these experiments. Family B may also be divided into 2 distinct groups.

The mean D0 value for the control cell lines was 4.5 J/sq m. This value was not significantly different to those for the sporadic melanoma cell lines (4.3 J/sq m) or the normally UV-sensitive groups (Group N) in Family A (4.2 J/sq m) and Family B (4.4 J/sq m).

However, the mean D0 values of sensitive groups (Group S) in Family A (2.4 J/sq m) and Family B (2.9 J/sq m) were significantly lower than those of both control and normally sensitive family members (p < 0.001, by the Wilcoxon-Mann-Whitney rank-sum test).

Individuals in Families A and B affected by melanoma are indicated in Charts 3 and 4, respectively. Those individuals considered to be abnormally UV sensitive are marked S, and normally sensitive individuals are marked N. In both families, no Group N individual had melanoma; all individuals with melanoma or multiple moles belonged to Group S. Sensitivity bore
no relation to age. In both groups, there was more than one sensitive member of each generation.

DNA Repair Synthesis. Following UV irradiation, DNA repair synthesis in UV-sensitive Group S cell lines [5.90 ± 1.22 (S.E.) x 10^4 cpm/10^6 cells] was similar to that carried out in controls [4.32 ± 1.72 x 10^4 cpm/10^6 cells] and Group N lines [5.56 ± 3.76 x 10^4 cpm/10^6 cells]. There was no evidence of a deficiency in repair synthesis as is seen in excision-deficient XP cells [4.10 ± 3.8 x 10^3 cpm/10^6 cells].

Unscheduled DNA Synthesis. The level of incorporation of [3H]thymidine in the non-S-phase cells was found to be similar in Group S cells and control cells. The mean number of grains per nucleus was significantly higher than background for these 2 cell lines, attesting to the presence of active unscheduled DNA synthesis. The mean number of grains per nucleus in the case of XP301 was not significantly different from background as has been reported in studies on XP-A cell lines (11).

Inhibition of DNA Replication. Following UV irradiation, DNA replication is inhibited in excision-deficient and variant XP cells, in Cockayne syndrome cells, and in the UV-sensitive cell line 11961 (5, 14, 21). The rates of DNA replication in representative normal, Group S, and XP cells after UV irradiation, compared with unirradiated controls, are shown in Chart 5. In the UV-sensitive cell lines FM136 and FM210, DNA synthesis was depressed to a minimum 2 hr after irradiation with 5 J/sq m and increased slowly to the levels in unirradiated samples of the same cell lines, after approximately 6 hr incubation; the same was true for all Group S cells tested (not shown). The XP301 cells showed a more severe depression of synthesis and failed to recover in the time of the experiment. DNA synthesis in C11 cells was slightly depressed but recovered to normal levels after approximately 4 hr incubation; the same was true for other control cells and for cells from Group N.

DISCUSSION

In the families described here, the pattern of occurrence of melanoma (Charts 3 and 4) is consistent with dominant inheritance and incomplete penetrance, a pattern frequently observed in familial melanoma (10). The pattern of UV sensitivity in these families is also consistent with dominant inheritance. Since the cells of those family members examined who had melanoma fell into the UV-sensitive class, it is possible that UV sensitivity directly confers a predisposition to the development of melanoma. However, the observation that some UV-sensitive individuals in the appropriate generations of both families do not have melanoma must be accounted for. This may simply reflect a latency period such that these UV-sensitive individuals...
will later develop melanoma or that an environmental factor which triggers the development of melanoma in sensitive individuals has not been encountered.

The association of UV sensitivity with melanoma could be accounted for by proposing that the UV-sensitive gene is closely linked to a hypothetical melanoma gene if we assume that the underlying defect in lymphoblasts is also present in melanocytes. Where UV sensitivity is found in individuals who do not have melanoma, the explanation may rest with time, chance, or chromosomal cross-over in that branch of the family, disassociating the UV sensitivity and melanoma genes. Conceivably, UV may act as a promoter in the genesis of melanoma in UV-sensitive family members, with the initiation step being provided by the melanoma gene. Other factors subject to genetic control and inheritance in these families and involved, for example, in the immune system (6) or endocrine system (17) may modify the development of melanoma in individuals carrying the UV sensitivity gene.

In general, UV sensitivity is not a prerequisite for the development of melanoma since the lymphoblastoid cell lines from a number of cases of sporadic melanoma were no more sensitive to the lethal effects of UV radiation than normal cells. The individuals with melanoma in the 2 pedigrees studied were different from sporadic cases in this respect.

The nature of the defect in the UV-sensitive familial melanoma cell lines remains to be elucidated. The normal level of DNA repair synthesis, measured autoradiographically or by scintillation counting, makes it unlikely that there is an excision repair deficiency such as that seen in XP. Normal repair synthesis has been reported previously in cell lines of a number of cases of sporadic melanoma (19). The finding of normal rates of DNA chain elongation following irradiation appears to exclude mutants of the XP variant type. However, the recovery of DNA replication in Group S cells after irradiation was delayed compared with normal controls. These data together suggest that Group S cells initiate fewer replicons following UV irradiation than do normal cells. The possibility that UV sensitivity might confer altered liability to UV-induced mutagenesis needs to be explored.

The finding of a dominant UV sensitivity in association with familial melanoma serves to stimulate further the study of genetic factors underlying susceptibility to this type of tumor. This observation does not imply that all familial melanomas will exhibit such an association; indeed, we would be surprised if this were so. However, a detailed examination of this group of mutants at a molecular level should contribute to the characterization of genetic factors involved in the genesis of melanoma and perhaps may ultimately be of prognostic value within certain families.
