ABSTRACT

A rat brain tumor model has been developed utilizing nude rats and the human melanoma cell line MRA 27. For pharmacokinetic and tissue distribution studies, 2 × 10⁶ MRA 27 cells were implanted intracerebrally (i.e.), and 30 days later, 120 mg of ¹⁰B-enriched l-boronophenylalanine was injected i.p. into nude rats. ¹⁰B concentrations in the tumor, blood, and normal brain were 23.7, 9.4, and 8.4 μg/g, respectively, 6 h following administration. For therapy experiments, tumor bearing rats were irradiated at the Brookhaven Medical Research Reactor 30 days following implantation. The median survival time was 44 days for untreated rats, 76 days for those receiving a physical dose of 2.7 Gy, and 93 days for those receiving 3.6 Gy. Animals receiving both ¹⁰B-l-boronophenylalanine and physical doses of 1.8, 2.7, or 3.6 Gy (total tumor physical doses of 5.0, 7.5, or 10.1 Gy) had median survival times of 170, 182, and 262 days, respectively. Forty % of rats that received the highest tumor dose (10.1 Gy) survived >300 days. In a replicate experiment 21% of animals that had received l-boronophenylalanine and irradiation (total tumor physical dose of 10.1 Gy) were alive 220 days after therapy. In a parallel study, animals that were irradiated with γ photons from a ¹³⁷Cs source with 12 Gy or 2.0 Gy 9 delivered to the head had median survival times of 86 and 79 days, respectively, compared to 47 days for untreated animals. Our results indicate that boron neutron capture therapy is effective against i.e. melanoma in a rodent model and suggest that large animal studies are warranted to further assess its efficacy.

INTRODUCTION

Malignant melanoma can metastasize to almost any organ of the body, but especially to the skin, liver, lung, and brain (1, 2). Patients with brain metastases have a very poor prognosis despite aggressive chemotheraphy and radiotherapy (3, 4). In one series of 125 patients, the median survival times of patients with cerebral metastases were 9 weeks when treated with a radiation dose of 30–40 Gy to the whole brain and 26 weeks when patients had surgical excision of solitary lesions, compared to 3 weeks if they were not treated (4). Immunotherapy using interleukin 2 and low doses of cyclophosphamide or active specific immunization resulted in a prolongation of the remission phase in patients with disseminated melanoma, although many of these patients eventually succumbed to their cerebral metastases (5).

One promising therapeutic modality for the treatment of brain tumors is boron neutron capture therapy (6), which has been recently reviewed (7). BNCT is a binary system based on selective uptake of sufficient amounts of a stable isotope, ¹⁰B, by tumor cells, followed by irradiation with low energy (0.025–0.5 eV) thermal neutrons. The resulting nuclear reaction yields α particles and recoiling ⁷Li nuclei, which have high linear energy transfer and path lengths of approximately one cell diameter (10–14 μm). In theory, this should minimize radiation effects to normal brain due to low uptake of ¹⁰B by normal tissues but result in a significant tumoricidal effect due to selective accumulation of ¹⁰B by neoplastic cells.

Mishima et al. (8, 9) have used the amino acid p-boronophenylalanine, a boron containing melanin precursor analogue, as a capture agent for the treatment of cutaneous melanomas in animals and humans. In most instances, the BPA was injected peripherally and allowed to clear from the surrounding normal skin, and then neutron irradiation was initiated. Codere et al. (10, 11) have demonstrated the efficacy of BNCT in cutaneous melanomas in mice, ocular melanoma in rabbits (12), and i.e. gliosarcomas in rats (13) using systemic injections of BPA. Furthermore, Saris et al. (14) recently have reported on the responsiveness of the murine glioma 261 to BNCT.

Although extensive animal studies have been carried out on the treatment of extracerebral malignant melanoma, to the best of our knowledge there is little, if anything, in the literature on the treatment of i.e. melanoma. We previously have reported that BNCT may have some potential as a modality to treat i.e. melanoma (15). The purpose of the present study was to expand upon our preliminary observations using BPA based BNCT and a human melanoma cell line implanted i.c. into nude rats.

MATERIALS AND METHODS

Animals and Tumor Cell Line. The human melanoma cell line MRA 27 was derived from a 60-year-old Norwegian male and has been propagated both in vitro and in vivo in nude mice and rats. MRA 27 cells were grown in McCoy's 5A medium (GIBCO, Grand Island, NY) supplemented with 10% fetal bovine serum (Hyclone, Logan, UT), 100 units/ml penicillin, 100 μg/ml streptomycin, and 2 mM l-glutamine and were tested periodically for mycoplasma contamination by DNA-fluorochrome staining and UV microscopy (Bionique Testing Laboratory, Saranac Lake, NY). Six to 8-week-old athymic female nude rats of NIH-rmu strain were purchased from the Animal Production Branch, National Cancer Institute, Frederick, MD. The rats were maintained under specific pathogen free conditions and fed sterilized food and water.

Implantation. A stereotactic implantation procedure, previously used by us for studies on BNCT of a rat glioma (16), has been implemented. Briefly, nude rats were sedated i.p. with a 1:2:1 mixture of 120 mg/kg of ketamine/20 mg/kg of xylazine and a plastic screw was embedded in the skull. MRA 27 cells were injected through a central hole in the plastic screw into the right caudate nucleus at a concentration of 10⁵ or 2 × 10⁶/10 μl of serum free McCoy's 5A medium containing 1% agarose with a gelling temperature of <30°C. The screw hole was filled with bone wax following withdrawal of the needle, and the operative field was flushed with betadine before closing the scalp incision with a single sterilized clip. The rats were weighed 3 times/week following

neutrons; BPA, boronophenylalanine; MW-M, megawatt-minute; PE, plating efficiency; RBE, relative biological effectiveness; MeST, median survival time(s); i.e., intracerebrally; n, neutrons; p, protons.
implantation and irradiation studies. The tumor volume was determined at the time of death from formalin fixed brains that had been cut coronally at 2-mm intervals. The tumor size index was defined as the cube root of the product of the largest measurements of the length, height, and width (16).

**Pharmacokinetics and Tissue Distribution Studies.** For injection, BPA (Cayley Chemical Co., Cayley, PA), as either the racemic α, or the purified l enantiomer, was converted to a more soluble fructose complex. BPA and fructose were mixed in a 1:1 molar ratio to yield a final concentration of 120 mg of BPA/2 ml of water. The pH was adjusted to 8.8 with 6 N NaOH. Two ml of the complex were administered i.p. to rats 37 days following i.c. implantation of 10⁶ tumor cells, unless indicated otherwise. Animals were killed 1, 3, 6, 9, 12, and 18 h later and samples of blood, brain, tumor, skin, liver, kidneys, muscles, eyes, and skull were obtained. Boron concentrations were determined by means of direct current plasma atomic emission spectroscopy, as described in detail elsewhere (17).

**In Vitro Cell Irradiations and Clonogenic Assays.** In *vivo* irradiations of MRA 27 cells were carried out at the Brookhaven Medical Research Reactor at 1 MW reactor power with an n₀ flux of 2.8 × 10¹⁰ neutrons/cm²·min. Prior to irradiation, cells were incubated for 24 h with BPA-fructose complex at a concentration of 10 μg ¹⁰B/ml of growth medium. As previously described (18), the same concentration of ¹⁰B was maintained in the medium during trypan blue staining, harvesting, and irradiation. The cells were irradiated at a density of 2 × 10⁶/µl at ambient temperature but were kept on ice during transportation until plated. Following irradiation, the cells were placed in boron free medium, plated into Petri dishes, and incubated at 37°C in a humidified atmosphere containing 5% CO₂. Forty days later the plates were washed with phosphate buffered saline, fixed with formaldehyde, and stained with 1% crystal violet. Colonies ≥ 50 cells (0.3-mm) were enumerated visually or by means of an Artek 880 image analyzer (Artek System Co., Farmingdale, NY). The plating efficiency:

\[
\text{PE} = \frac{\text{Number of MRA 27 colonies enumerated}}{\text{Total number of MRA 27 cells plated}} \times 100\%
\]

ranged from 30 to 50%. The surviving fraction was determined from:

\[
\frac{\text{Total number of MRA 27 cells plated}}{\text{Number of colonies enumerated}} \times \text{PE/100}
\]

In *vivo* X-irradiations were carried out using a Stabilipan 250 kVP x-ray machine. The 250 kVP X-irradiations were performed at 15 mA with a Theresus 1 filter and 50 cm SSD at a dose rate of 0.51 Gy/min. Cells were irradiated in boron free medium and boron containing medium and were assayed as described above.

**In Vivo Irradiation Studies.** All irradiations were carried out at the Brookhaven Medical Research Reactor. The reactor power was maintained at 1.25 MW during the irradiation of all rats. BNCT was initiated 30 days following stereotactic implantation of 2 × 10⁶ MRA 27 cells. Rats were divided into 6 groups of 9 or 10 animals each. Groups 1 and 2 received 6 or 8 MW-minutes of irradiation, respectively. Groups 3–5 received 4, 6, or 8 MW-M of irradiation 6 h following i.p. administration of 120 mg of 95% ¹⁰B-enriched l-BPA. Group 6 served as untreated controls. All rats were anesthetized with a 1:2:1 mixture of ketamine/xylazine and placed supine in a body shield-head stabilizer, as described elsewhere (13, 19, 20). The tumor implantation site was centered in the 1.15-cm diameter aperture of the neutron beam collimator. The adjustment of the head of the rat was established using a marked lucite plate as a template for the collimated beam.

γ-irradiations were performed 31 days following implantation of 2 × 10⁶ MRA 27 cells. Rats were divided into 3 groups of 5 or 6 animals each. Group 1 received a single 12-Gy dose of γ photons and group 2 received 9 fractions of 2.0 Gy each, delivered over an 11-day period using a Picker 173Cs teletherapy machine, which delivered 1.0 Gy/min at 15 cm SSD when a 2-cm (outside diameter) cone was used. Group 3 was untreated controls. The tumor bearing region of the head of the rat was irradiated directly and the body was shielded with 5 mm of lead.

**Dosimetry.** The mixed radiation in tissue during *in vivo* or *in vitro* BNCT includes n₀ and fast neutrons (>10,000 eV), γ photons, and heavy particles that are generated from ¹⁴N(n,p)⁴C and ¹⁰B(n,α)⁷Li reactions. As previously described (13, 18, 20), n₀ fluences were measured using 3-mm long gold wires implanted into the brain of a dead rat to a depth of 4–5 mm below the skull surface, or alternatively the wires were placed inside 1.5 ml Eppendorf microfuge tubes for *in vitro* irradiations. The n₀ flux at a depth of 4–5 mm below the skull was 3.9 × 10¹¹ neutrons/cm²·min (±5%) and 2.8 × 10¹¹ neutrons/cm²·min (±5%) for *in vivo* irradiations at 1 MW power. The dose contributions from the ¹⁰B(n,α)⁷Li and ¹⁴N(n,p)⁴C reactions were calculated using data from the measured n₀ flux, assuming uniform boron distribution and a nitrogen content of 2.6% in vivo and 1.5% in vitro (13, 18, 20, 21). The γ photons and fast neutron components were measured using tissue equivalent plastic chambers (A-150 plastic; Far West Technology, Goleta, CA) with TE gas (Rosti gas) and graphite chambers filled with CO₂. The dosimetry of each component for both *in vivo* and *in vitro* irradiations are summarized in Table 1.

The extrinsic γ photons and fast neutron doses were measured by using paired tissue equivalent plastic chambers (A-150 plastic) with TE gas (Rosti gas) and graphite chambers filled with CO₂. The dose rates for each component are tabulated in Table 1. The γ photon dose rate for 137Cs was measured by means of an exposure rate meter model 192X (Capintec, Montvale, NJ) with a 0.6-ml Farmer replacement ionization chamber (PR-063).

**Statistical Analysis.** The Wilcoxon-Gehan rank sum two sample test was applied to the survival data to test for significant differences between the treated groups and controls. All censored rats were ranked equally.

**RESULTS**

**Pharmacokinetics and Tissue Distribution Studies.** Blood, brain, and tumor concentration-time profiles of boron after a single i.p. injection of 120 mg of α-BPA (6.3 mg of B) in nude rats carrying i.c. MRA 27 melanoma are shown in Fig. 1. Pharmacokinetic analysis was performed on the geometric mean of blood boron concentrations using a nonlinear regression program. Blood boron concentration peaked at the first sampling time (1 h) indicating rapid absorption of BPA from the peritoneal cavity. Blood boron levels exhibited biexponential decay and, consequently, were fitted to a classical two compartment open system with first order elimination from the central compartment and with the assumption of a rapid (0.1 min) zero-order input. The half-life of the rapid disposition phase, t₁/₂a was 0.91 h and the half-life of the slow disposition phase, t₁/₂b was 5.3 h. The apparent total body blood clearance of 520 ml/min reflects a rapid elimination of boron from the body assuming the extent of bioavailability from the i.p. injection was essentially 1. The apparent volumes of distribution of the central compartment (61 ml), at the steady state (118 ml), and at equilibrium (239 ml) for rats having a mean body weight of 150 g are relatively large, indicating extensive tissue binding of BPA.

Tumor levels of boron, however, exhibited monoexponential decay (t₁/₂d = 5.6 h) with the terminal time points (6–18 h) in an apparent distribution equilibrium with boron levels observed in the blood. Tumor to blood boron concentration ratios within the terminal phase ranged 2.4–3.8. Normal brain boron concentrations peaked at 6–9 h after BPA administration and then declined monoexponentially. These values were almost the same as the blood boron concentrations. Tumor to normal brain boron concentration ratios within the terminal log-linear phase averaged 2.4.

The best composite ratio for BNCT was observed 6 h post-administration of α-BPA. At that time the tumor boron concentration was 13.7 μg/g of tissue and tumor to blood boron concentration and tumor
change in the survival of MRA 27 cells was observed when irradiated to 37% (estimated from the final slope), (0.66 to 0.14 Gy) was observed following reactor irradiation alone or in the presence of 10 \( \mu \)g of \( ^{10}\)B (\( ^{10}\)B-BPA). The PE for MRA 27 cells did not change when preincubated with IOB-BPA. When 10 \( \mu \)g/ml of 10B (IOB-BPA) were present at ambient conditions during cell irradiations, a remarkable drop in the dose required to decrease the surviving fraction was seen following reactor irradiation alone or in the presence of 10 \( \mu \)g of 10B (Fig. 2). This reduction was attributed primarily to the high linear energy transfer of the \( ^{10}\)B(n,a)\(^7\)Li reaction. Furthermore, no change in the survival of MRA 27 cells was observed when irradiated with 250 kVp x-rays in the presence of 10 \( \mu \)g/ml of \( ^{10}\)B (Fig. 2).

### BNCT Irradiation Studies
 BNCT was initiated 30 days following i.c. implantation of \( 2 \times 10^5 \) MRA 27 cells. The tumor size index at the time of irradiation was approximately 5.3 mm. The calculated doses in Gy (physical dose) and Gy-Eq delivered to the tumor, blood, and brain are summarized in Table 3. The physical doses represent the contributions of fast neutrons, \( \gamma \) photons, \(^{14}\)N(n,p)\(^{14}\)C, and \(^{10}\)B(n,\(\alpha\))\(^7\)Li reactions. In order to convert the physical dose to the equivalent dose, an RBE of 2.3 was assumed for the \(^{10}\)B(n,\(\alpha\))\(^7\)Li reaction and an RBE of 2 for fast neutrons and the \(^{14}\)N(n,p)\(^{14}\)C reaction (13, 18, 20–22).

Kaplan-Meier plots for BNCT treated animals and the irradiated controls are shown in Fig. 3. All untreated rats (group 6) died by 63 days following implantation and had a tumor size index of 8.0 \( \pm \) 0.7. The MeST for group 6 was 44 days compared to 76 days for group 1 (6 MW-M) and 93 days for those animals in group 2 (8 MW-M). Animals from BNCT groups 3–5 had MeSTs of 170, 182, and 262 days, respectively. Ten months following tumor irradiation, 40% of the rats from group 5 (BPA + 8 MW-M) were still alive and appeared to be in a good condition (Table 4).

The prolongation of survival times for all irradiated rats (groups 1–5) compared to untreated rats (group 6) were highly significant (\( P < 0.001 \)). The percentages of survival at 100, 150, and 200 days for BNCT treated rats (groups 3–5) were 70–80%, 50–70%, and 20–60% compared to 33%, 22–30%, and 22–30%, respectively, for the irradiated controls (groups 1 and 2). These percentages of survival were significantly different at 100 and 150 days (0.05 \( \geq P > 0.005 \)) with the exception of group 3 (BPA + 4 MW-M), which was not significant at 150 days.

Another BNCT experiment was initiated 23 days following stereotactic implantation of \( 2 \times 10^5 \) MRA 27 cells. The untreated controls (\( n = 10 \)) had a MeST of 37 and 66 days for those (\( n = 15 \)) receiving irradiation dose (no BPA) of 3.6 Gy or 6.4 Gy-Eq (8 MW-M). The MeST for the BNCT group (BPA + 8 MW-M), which received a tumor dose of 10.1 Gy or 21.2 Gy-Eq, was 154 days and 3 out of 14 rats were still alive 220 days following tumor irradiation (Fig. 4). The enhanced survival of the BNCT treated rats was statistically significant compared to untreated (\( P

* Boron concentrations were determined by means of direct current plasma atomic emission spectroscopy. The mean ± 1 SD represents 4 rats.

### In Vitro Survival Studies
 The cell survival curves of MRA 27 following irradiation with 250 kVp x-rays or at Brookhaven Medical Research Reactor are shown in Fig. 2. The dose response curve for 250 kVp x-rays clearly demonstrates a shoulder, whereas none was seen following reactor irradiation alone or in the presence of 10 \( \mu \)g \( ^{10}\)B/ml (\( ^{10}\)B-BPA). The PE for MRA 27 cells did not change when they were preincubated with \( ^{10}\)B-BPA. When 10 \( \mu \)g/ml of \( ^{10}\)B (\( ^{10}\)B-BPA) were present at ambient conditions during cell irradiations, a remarkable drop in the dose required to decrease the surviving fraction to 37% (estimated from the final slope), (0.66 to 0.14 Gy) was observed (Fig. 2). This reduction was attributed primarily to the high linear energy transfer of the \( ^{10}\)B(n,\(\alpha\))\(^7\)Li reaction. Furthermore, no change in the survival of MRA 27 cells was observed when irradiated with 250 kVp x-rays in the presence of 10 \( \mu \)g/ml of \( ^{10}\)B (Fig. 2).

appears to be very important in this brain tumor model, since prior to death rats usually demonstrate a dramatic weight loss of approximately 40 g in 3–4 days. Long term surviving animals from both experiments eventually were sacrificed, and there was no evidence of residual tumor, suggesting a complete cure.<sup>5</sup>

γ-Irradiation Studies. Kaplan-Meier plots for rats implanted i.e. with 2 × 10⁶ MRA 27 and then treated 31 days later with γ photons are shown in Fig. 5. The MeSTs for rats treated with 12 Gy and 2.0 Gy × 9 were 86 and 79 days, respectively, compared to 47 days for the untreated animals. These differences in survival were significant at P < 0.01 for both irradiated groups compared to untreated animals. However, there was no significant differences between the γ-irradiated groups.

DISCUSSION

In the present study BNCT was used to treat nude rats carrying i.e. human melanoma with 10B-L-BPA as the capture agent. BPA-fructose complex was administered systemically and showed selectivity for the tumor compared to the normal brain and blood, which confirms other previously reported results (8–15). 10B-BPA concentration in the tumor was 23.7 µg 10B/g and was within the range (15–30 µg/g) considered for BNCT to be effective (7). The 1.8× higher uptake of the physiological l isomer compared to the α racemic mixture suggests that 10B-BPA accumulated in the tumor through a metabolic pathway and not by diffusion and is similar to data reported by Codere et al. (24).

Prolongations of survival times were observed in a dose dependent relationship with all radiation doses, and the higher the calculated radiation dose, the greater the MeST. This was shown with the three BNCT treated groups and was similar to our preliminary results (15). Seventy to 80% of all BNCT treated rats showed long term survival (>100 days) compared to 22–30% for irradiated controls. Forty % of rats treated with BPA + 8 MW-M (21.2 Gy-Eq) were still alive and in good condition 300 days following tumor implantation. In the second experiment, no rats from the irradiated control that had received 3.6

<sup>5</sup> K. Z. Matalka, manuscript in preparation.
crosis of both the white and gray matter, vascular thrombosis, fibrin deposition and polymorphonuclear cell infiltrates in the wall of blood vessels, demyelination, and reactive gliosis (30). This was primarily due to the boron compounds used, which were not selectively accumulated by tumors. In the present study, however, the difference in the concentrations of $^{10}$B-BPA in the tumor versus normal brain and blood resulted in radiation doses to the brain (5.8–11.6 Gy-Eq) and blood (6.1–12.3 Gy-Eq) that were 1.8 and 1.7 times less than those delivered to the tumor. This illustrates the potential advantage of BPA based BNCT over other forms of radiation therapy. Calvo et al. (31) have reported that necrosis of the cerebral white matter developed in rats 36 weeks following a single dose of $\gamma$ radiation. However, doses of less than 12 Gy, as in the present study, were considered to be tolerable by the brain parenchyma (32, 33). At the present time we are in the process of studying the late radiation effects produced in the rat brain by BNCT following administration of BPA. This should provide information on the normal tissue tolerance of the brain parenchyma and cerebral vasculature following BNCT.

Our data suggest that BPA has promise as a capture agent for BNCT of melanoma metastatic to the brain, but prior to the initiation of any clinical studies, it is essential that the therapeutic efficacy should be determined in a large animal model. Furthermore, it is essential that the long term radiation effects, which may be produced in normal brain following BNCT, be clearly defined.

Boron Neutron Capture Therapy of Intracerebral Melanoma Using Boronophenylalanine as a Capture Agent

Khalid Z. Matalka, Michael Q. Bailey, Rolf F. Barth, et al.
