Abstract
To identify genes whose expression patterns are altered by methylation of DNA, we established a method for scanning human genomes for methylated DNA sequences, namely bacterial artificial chromosome array-based methylated CpG island amplification (BAMCA). In the course of a program using BAMCA to screen neuroblastoma cell lines for aberrant DNA methylation compared with stage I primary neuroblastoma tumors, we identified CpG methylation-dependent silencing of the nuclear receptor 1I2 (NR1I2) gene. NR1I2 was methylated in a subset of neuroblastoma cell lines and also in advanced-stage primary tumors with amplification of MYCN. Its methylation status was inversely associated with gene expression. Treatment with the demethylating agent 5-aza-2′-deoxycytidine restored NR1I2 transcription in neuroblastoma cell lines lacking endogenous expression of this gene. A CpG island located around exon 3 of NR1I2 showed promoter activity, and its methylation status was clearly and inversely correlated with NR1I2 expression status. The gene product, NR1I2, has a known function in regulating response to xenobiotic agents but it also suppressed growth of neuroblastoma cells in our experiments. We identified some possible transcriptional targets of NR1I2 by expression array analysis. The high prevalence of NR1I2 silencing by methylation in aggressive neuroblastomas, together with the growth-suppressive activity of NR1I2, suggests that this molecule could serve as a diagnostic marker to predict prognosis for neuroblastomas. (Cancer Res 2005; 65(22): 10233–42)

Introduction
Neuroblastoma, the most common extracranial solid tumor of childhood, has distinct biological characteristics in different prognostic subgroups. Children (>12 months at diagnosis) with stage IV or MYCN-amplified stage III tumors are at high risk of mortality (>60%), children with non-MYCN-amplified local-regional tumors (i.e., stages I, II, and III) and infants (<12 months at diagnosis) with stage IVS disease are generally at low risk of mortality (<10%), and infants with stage IV disease and children with stage III disease without MYCN amplification are at intermediate risk (1, 2), although the biological basis for that clinical diversity remains unclear. In addition to genetic changes including the MYCN amplification, epigenetic alterations often play important roles in the pathogenesis of human cancers, including neuroblastoma (3). For example, hypermethylation of promoter sequences of CASP8, RASSF1A, CD44, TSP-1, and HSP47 genes has been observed in neuroblastoma tumors (4–8), and silencing of CASP8 through methylation of its promoter tends to be associated with MYCN amplification (4). A reported positive correlation between promoter hypermethylation of CASP8 and RASSF1A (5) suggests that hypermethylation of multiple genes may influence the phenotype of neuroblastoma.

Because hypermethylation in CpG-rich promoter or exonic regions seems to be a critical contributor to inactivation of tumor suppressor genes in many human cancers through transcriptional silencing (9), identification of hypermethylated CpG-rich sequence in cancer cell genomes could accelerate identification of unknown tumor suppressors. Although several techniques, including a method known as methylated CpG island amplification (MCA), have been developed (10, 11), we still have limited number of effective and practical high-throughput methods for genomewide screening of aberrantly methylated CpG-rich sequences. To accomplish high-throughput screening for methylated sites in the entire genome, we developed a bacterial artificial chromosome (BAC) array-based MCA (BAMCA), incorporating our custom-made, BAC-based genomic DNA array combined with MCA (12).

In an effort to identify genes that are silenced by methylation mechanisms and associated with progression of neuroblastoma, we applied BAMCA to human neuroblastoma in the study reported here. Because the pattern of genomic changes observed in most neuroblastoma-derived cell lines is similar to that of advanced primary neuroblastomas (13), we used DNAs from neuroblastoma cell lines and from stage I primary tumors as test and reference samples, respectively. Using this approach, we successfully identified one gene, nuclear receptor 1I2 (NR1I2), also known as PXR, whose expression was decreased in a subset of
human cell lines and tumors of neuroblastoma through hyper-
methylation of a CpG island showing promoter activity. \textit{NR1I2}
was methylated and silenced mainly in late-stage neuroblastoma
tumors with \textit{MYCN} amplification and in older children. Exogenous restoration of \textit{NR1I2} expression suppressed growth of neuroblastoma cells lacking endogenous expression of the gene.

Materials and Methods

Cell culture, drug treatment, and primary tissue samples. All 19 human neuroblastoma cell lines we used (SK-N-KS, SK-N-AS, SK-N-SH, SK-N-DZ, SH-SY5Y, MP-N-NS, MP-N-MS, KP-N-IFK, KP-N-SILA, KP-N-TK, KP-N-Y, SMS-KCN, SMS-KAN, SJ-N-CG, NB-1, CHP134, IMR32, and GOTO) had been established from surgically resected tumors and maintained as described previously (13). These cultures
Adaptors were ligated to digested with 100 units of a methylation-sensitive restriction enzyme Toyota et al. (11). Five-microgram aliquots of test DNA were first methylated regions was carried out by the MCA method described by methylated alleles. (region 1; Fig. 1 http://www.aacrjournals.org). (9B11; Cell Signaling Technology, Beverly, MA). For colony formation assays, transfected cells were selected with 500 μg/mL G418; 3 weeks after transfection, the neomycin-resistant colonies were stained with crystal violet and counted (17).

Cell growth assay. Stable NR1I2 transfectants and controls were obtained by transfecting pCMV-Tag3-VP-NR1I2 or pCMV-Tag3-mock, respectively, into cells lacking NR1I2 expression. For measurements of cell growth, 2 × 10^4 cells were seeded in 96-well plates. The numbers of viable cells were assessed by a colorimetric water-soluble tetrazolium salt assay (cell counting kit-8; Dojindo Laboratories, Kumamoto, Japan).

Oligonucleotide array analysis. mRNA expression profiling was done using the AceGene Human oligo chip 30K (DNA Chip Research, Inc., Kanagawa, Japan), containing 30,000 genes, as described elsewhere (18). The test and reference cDNA probes labeled with aminooallyl-dUTP (Ambion, Inc., Austin, TX) were synthesized using oligot(dT)12-18 primer and coupled with Cy3- or Cy5-monoreactive dye (Amersham Biosciences, Tokyo, Japan), respectively. The hybridized chips were scanned using GenePix 4000B (Axon Instruments) and analyzed using GenePix Pro 4.1 software (Axon Instruments). Signal intensities between the two fluorescent images were normalized by the averaged values for blank spots; this procedure effectively defined the signal intensity-weighted spot for the internal controls of housekeeping genes on each array to have a Cy3/Cy5 ratio of 1.0.

Results

Methylation analysis of neuroblastoma cell lines by bacterial artificial chromosome array-based methylated CpG island amplification. To assess DNA methylation in the more advanced type of neuroblastoma tumors, we did BAMCA

Identification of NR1I2 Silencing by BAMCA

![Figure 1](https://example.com/figure1.png)

**Figure 1.** Methylation status and expression levels of NR1I2 in neuroblastoma (NB) cell lines. A, BAMCA procedure. The DNAs from neuroblastoma cell lines (test) or stage I neuroblastoma tumors (control) were first digested with Smal in the blunt end and subsequently with XmaI in the sticky end (blue boxes). Adaptors were ligationd to XmaI-digested sticky ends (pink boxes) and PCR was done with an adaptor primer and Cy3-dCTP (test) or Cy5-dCTP (control) for labeling. Labeled PCR products were cohybridized to our in-house array (MCG Whole Genome Array-4500; ref. 12). Hybridizations were carried out as described elsewhere (17). Arrays were scanned with a GenePix 4000B (Axon Instruments, Foster City, CA) and analyzed using GenePix Pro 4.1 software (Axon Instruments).

Reverse transcription-PCR and real-time quantitative reverse transcription-PCR. Single-stranded cDNAs were generated from total RNAs (17) and amplified with specific primers for each gene. Primer sequences are available on request. Real-time quantitative PCR was done using LightCycler (Roche Diagnostics, Tokyo, Japan) with SYBR green as described previously (18). The glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene served as an endogenous control. Each sample was normalized on the basis of its GAPDH content. PCR amplification was done in duplicate for each sample.

Methylation analysis. To investigate methylation of DNA, the method of combined bisulfite restriction analysis (COBRA) was done as described earlier (11). Genomic DNAs were treated with sodium bisulfite and subjected to PCR using primer sets designed to amplify the regions of interest. PCR products were digested with HhaI, which recognizes sequences unique to the methylated alleles but cannot recognize unmethylated alleles, and electrophoresed. For bisulfite sequencing, PCR products were subcloned and sequenced.

**Reporter assay.** A 1,080 bp fragment upstream of exon 1 of NR1I2 (region 1; Fig. 1A) and a 480 bp fragment of a CpG island that includes exon 3 (region 2; Fig. 1A) were ligated into the pGL3-Basic vector (Promega, Madison, WI) in front of and/or downstream of the luciferase gene. An equal amount of each construct was introduced into cells with an internal control vector (pRI-I-κB, Promega), using FuGENE 6 (Roche Diagnostics). A pGL3-Basic vector without insert served as a negative control. Firefly luciferase and Renilla luciferase activities were each measured 36 hours after transfection using the Dual-Luciferase Reporter Assay System (Promega); relative luciferase activities were calculated and normalized versus Renilla luciferase activity.

**Transfection, Western blotting, and colony formation assays.** A full-length NR1I2 cDNA was cloned into the pCMV-Tag3 eukaryotic expression vector (Stratagene, La Jolla, CA) with or without etoposide (VP-16) in-frame along with the Myc epitope. A plasmid expressing a Myc-tagged NR1I2 with or without VP-16 (pCMV-Tag3-VP-NR1I2 or pCMV-Tag3-mock-NR1I2), or the empty vector (pCMV-Tag3-mock), were transfected into cells using FuGENE6 (Roche Diagnostics). Expression of NR1I2 protein in transfected cells was confirmed by Western blotting using anti-Myc-Tag antibody (9B11; Cell Signaling Technology, Beverly, MA). For colony formation assays, transfected cells were selected with 500 μg/mL G418; 3 weeks after transfection, the neomycin-resistant colonies were stained with crystal violet and counted (17).

Stable NR1I2 transfectants and controls were obtained by transfecting pCMV-Tag3-VP-NR1I2 or pCMV-Tag3-mock, respectively, into cells lacking NR1I2 expression. For measurements of cell growth, 2 × 10^4 cells were seeded in 96-well plates. The numbers of viable cells were assessed by a colorimetric water-soluble tetrazolium salt assay (cell counting kit-8; Dojindo Laboratories, Kumamoto, Japan).

* CpG islands were searched using NCBI human genome database (http://www.ncbi.nlm.nih.gov/).
† Each Cy3-labeled neuroblastoma cell line sample/Cy5-labeled mixed stage I neuroblastoma tumor samples (see Fig. 1A).
‡ Methylation status in primary tumors was determined by using bisulfite-PCR analysis (see Fig. 2A).
§ When we examined NR1I2 expression in our panel of 19 neuroblastoma cell lines by reverse transcription-PCR (RT-PCR; Fig. 1C), no NR1I2 mRNA was detected in 14 of the lines (73%): in
11 of 12 MYCN amplified lines (91%) or in 3 of 7 MYCN nonamplified lines (43%). One line, MP-N-TS, lacking expression of NR1I2 and without MYCN amplification, does show c-MYC amplification (13). Normal adrenal gland, which is considered the tissue of origin for neuroblastoma tumors, expressed NR1I2 mRNA.

Analysis of NR1I2 expression in neuroblastoma cell lines.
When we examined NR1I2 expression in our panel of 19 neuroblastoma cell lines by reverse transcription-PCR (RT-PCR: Fig. 1C), no NR1I2 mRNA was detected in 14 of the lines (73%): in 11 of 12 MYCN amplified lines (91%) or in 3 of 7 MYCN nonamplified lines (43%). One line, MP-N-TS, lacking expression of NR1I2 and without MYCN amplification, does show c-MYC amplification (13). Normal adrenal gland, which is considered the tissue of origin for neuroblastoma tumors, expressed NR1I2 mRNA.

To investigate whether demethylation could restore NR1I2 mRNA in neuroblastoma cells lacking endogenous expression, we treated cells with 1 µmol/L of 5-aza-dCyd, a methyltransferase inhibitor, for 5 days. Expression of NR1I2 mRNA was remarkably increased after the treatment (Fig. 1D).
Methylation of \( NR1I2 \) CpG island in neuroblastoma cell lines. We next examined the methylation status of the slightly CpG-rich 5' region (region 1) and the CpG island including exon 3 (region 2) of the \( NR1I2 \) gene, which had been detected by the National Center for Biotechnology Information (NCBI) human genome database\(^6\) as shown in Fig. 1E. Bisulfite sequencing analysis of region 2 revealed aberrant DNA hypermethylation in IMR32 and SH-SY5Y cell lines lacking expression of \( NR1I2 \), but hypomethylation in two lines expressing the gene (SK-N-AS and SK-N-KP) and in a normal lymphoblast cell line (LCL). On the other hand, no significant difference in methylation pattern within region 1 was observed among those four neuroblastoma cell lines and LCL, regardless of expression status. We did COBRA to confirm the relationship between expression and methylation status within region 2 in a larger set of neuroblastoma cell lines. Predominant methylated alleles were detected in all lines lacking \( NR1I2 \) expression (Fig. 1F and data not shown).

Because several splicing variants of \( NR1I2 \), including the variant starting transcription from exon 3 (variant 4, v4), have been reported in various human tissues (19),\(^7\) we did RT-PCR using specific primers for each variant to examine which transcripts might be silenced through a DNA methylation within region 2 in neuroblastoma cell lines (Fig. 1G). Variant 1, the most major variant in various human tissues, and variant 2 were expressed in unmethylated neuroblastoma cell lines, but not in methylated lines, whereas variant 4 without open reading frame was not expressed in one of the unmethylated cell lines (SK-N-AS). The expression of variant 1 and variant 4 was restored after the treatment with 5-aza-dCyd in methylated neuroblastoma cell lines, whereas the expression of variant 2 was not. Variant 3, lacking a part of exon 5, was not expressed in neuroblastoma cell lines regardless of methylation status within CpG island and 5-aza-dCyd treatment. Those results suggested that the methylation of CpG residues in region 2 might be mainly responsible for the silencing of variant 1 of the \( NR1I2 \) gene starting transcription from exon 1a in neuroblastoma, although region 2 does not contain its transcriptional start site.

Promoter activity of the CpG island located around exon 3 of \( NR1I2 \). Because the CpG island (region 2) of \( NR1I2 \) was located around exon 3, we first determined whether region 2 had promoter activity by means of a luciferase reporter assay. This fragment alone (Fig. 2A, 2/L) revealed clear promoter activity, whereas region 1 fragment upstream of exon 1 (Fig. 2A, 1/L) showed almost none (Fig. 2B). In addition, we next determined whether region 2 acts as an enhancer to stimulate transcription from exon 1 by testing the luciferase activity in construct

---

containing region 1 in front of the luciferase reporter gene and region 2 downstream of the luciferase gene (Fig. 2A, 1/L/2).

Although region 2 downstream of the luciferase gene (Fig. 2A, L/2) showed some promoter activity, region 2 revealed no enhancer activity for region 1 (Fig. 2C).

Analysis of NR1I2 methylation and expression in primary neuroblastoma tumors. We next examined methylation status of the NR1I2 CpG island in 51 surgically resected primary neuroblastomas using COBRA (Table 2). Clearly methylated alleles were detected in nine of the tumors (17%; Fig. 3A). The appearance of partial methylation observed in those nine tumors can be explained by the unavoidable contamination of non-tumorous cells in the specimens. Five of the nine tumors (55%) had undergone MYCN amplification, whereas only 3 of 42 (7%) unmethylated tumors showed amplification of MYCN (Table 2). Moreover, methylation of region 2 of the NR1I2 gene was more frequently detected in advanced tumors (stages III and IVa; \( P = 0.0234 \), Fisher’s exact test), tumors from patients with poor outcome (dead from disease; \( P = 0.0135 \), Fisher’s exact test), and tumors from patients >1 year old (\( P = 0.052 \), Fisher’s exact test), although the difference did not quite reach statistical significance in terms of patient age. In the 47 neuroblastoma cases where high-quality RNAs were available for expression analysis, a clear correlation between the methylation status of the CpG island and expression level of NR1I2 mRNA was observed (Fig. 3B and C). By means of real-time quantitative RT-PCR experiments, we saw a statistically significant inverse correlation between expression of NR1I2 mRNA and tumor stage (\( P = 0.0137 \), Mann-Whitney U test) or MYCN amplification (\( P = 0.0003 \), Mann-Whitney U test; Fig. 3C).

Suppression of cell growth after restoration of NR1I2 expression. To gain further insight into the potential role of NR1I2 in neuroblastoma carcinogenesis, we investigated whether restoration of NR1I2 expression would suppress growth of neuroblastoma cells lacking endogenous NR1I2 expression using two NR1I2 expression constructs, a Myc-tagged full coding sequence of NR1I2 alone (pCMV-Tag3-NR1I2) and one fused to the constitutively active herpes virus VP-16 transactivation domain (pCMV-Tag3-VP-NR1I2). The VP-16-NR1I2 chimeric protein showed stronger transactivating activity than NR1I2 alone in a reporter assay using a reporter construct containing NR1I2 response elements from the CYP3A4 promoter (data not shown). After selecting drug-resistant colonies in transient transfection experiments, we found that colonies of NR1I2-transfected cells were remarkably fewer than in cultures of control transfectants and the effect of VP-16-NR1I2 was much greater than that of NR1I2 (Fig. 4A).

NOTE: Statistically significant values are in boldface.
*COBRA was done as described in Materials and Methods.
\( P \) values are from Fisher’s exact test and were statistically significant when \( <0.05 \).
\( \dagger \)Tumor stage was classified according to the International Neuroblastoma Staging System.
established from a cell line (SMS-KAN) without endogenous expression of this gene showed a lower growth rate than control vector-transfected cells regardless of VP-16-NR1I2 expression level (Fig. 4B and C). The same result was obtained in other cell line (data not shown).

**Screening of possible target genes for NR1I2.** To identify possible transcriptional targets for NR1I2, we did expression array analysis in an independent VP-16-NR1I2 stable transfectant established from SMS-KAN, in a comparison with vector-transfected cells. We twice obtained independent experimental data (first, Cy3-B1/Cy5-vector; second, Cy5-B1/Cy3-vector) and compiled a list of 105 genes that showed ratios > 1.5 in both experiments (Supplementary Table S1). Semi-quantitative RT-PCR analysis revealed up-regulation of CYP3A4, a known transcriptional target of NR1I2, in VP-16-NR1I2 stable transfectant, indicating the reliability of our system for detecting target genes (Supplementary Fig. S1). To validate the expression array data, we did semi-quantitative RT-PCR analyses of 10 other genes (Fig. 4D), which have been previously reported as tumor-associated genes, using two independent VP-16-NR1I2 stable transfectants established from SMS-KAN cells (KAN-B1 and KAN-B2) and one stable transfectant from GOTO cells (GOTO-A1). GOTO-A1 also showed a lower growth rate than control vector-transfected cells (data not shown). The RT-PCR results for KAN-B1 confirmed up-regulation of seven genes except for BARD1, EXT1, and MCM5 (Fig. 4D). Notably, only PLA2G2A showed increased expression in all stable transfectants examined compared with their control cells (Fig. 4D; Supplementary Fig. S1).

**Discussion**

In the study presented here, we identified a novel target for CpG island methylation, NR1I2, observed mainly in advanced neuroblastomas, through a genome-wide exploration of highly methylated DNA fragments using BAMCA. A clear inverse correlation emerged between CpG island methylation and the expression status of NR1I2 both in cell lines and primary tumors of neuroblastoma (i.e., hypermethylation and silencing of NR1I2 were more frequent in advanced neuroblastoma tumors). Together with a shown growth suppressive effect of exogenous NR1I2, the data suggested that NR1I2 was likely to be a tumor suppressor gene associated with clinical and/or biological aggressiveness of neuroblastoma. Our results further underscored the promise of BAMCA as a high-throughput screening method for methylated sites in cancer genomes on an array platform.

BAMCA, however, has some disadvantages: (a) It examines only a limited number of CpG sites within a CpG island because only Smal/Xmal sites are used to search differentially methylated CpGs. (b) It identifies BACs, which contain differentially methylated sequences between test and reference DNAs, although sequences are not always associated with promoter regions of genes. (c) It misses differentially methylated sequences genes without BACs spotted on the BAC array used. To improve the sensitivity of array-based methylation screening, it is possible to use other methylation-sensitive restriction sites as indicators, including NolI site (20). However, BAMCA may quickly provide the list of possible target genes for methylation within identified BAC clones using information from human genome database without cloning and sequencing of enriched fragments, suggesting that it may have important applications in population-based studies of CpG island methylation.

NR1I2 locates at 3q13.33, a chromosomal region that is not often involved in loss of heterozygosity or copy number losses in neuroblastoma (21, 22). Indeed, most of the cell lines we used in this study showed normal copy number in 3q (13), suggesting that a homozygous inactivation of NR1I2 might occur by biallelic
methylation. Similar findings have been reported for several genes, such as RASSF1 (3p21.3), DAPK (9q34.1), and THBS1 (15q15), which are located in regions not frequently deleted, although some methylated genes, such as ARF and INK4A (9p21), and CASP8 (2q23), are in fact on regions frequently deleted in neuroblastoma.

Therefore, both biallelic methylation and monoallelic methylation with allele loss may be important mechanisms for inactivating tumor-associated genes in this disease.

Our promoter assays showed that CpG island around exon 3 (region 2) shows promoter activity, but CpG-rich 5' region containing exon 1 and its 5' upstream sequences (region 1) does not. Region 2 shows no enhancer activity for region 1 (Fig. 2). The methylation status of region 2, but not region 1, was highly and inversely correlated with the expression of NR1I2, especially the most major variant of NR1I2, variant 1, starting from exon 1a.

Those results suggest that the methylation status of CpG residues in region 2 might be responsible for the silencing of this gene and contributed to loss of function of NR1I2 protein in neuroblastoma.

A few studies, including ours, have shown that promoter activity can occur in fragments, especially CpG islands, not containing transcriptional starting sites (17, 24, 25). It is possible that methylation that occurred in those CpG islands with promoter activity may silence gene expression from specific starting sites.
Among numerous hypermethylated genes reported in neuroblastoma (3–8), CASP8 seems to be inactivated through promoter methylation in advanced neuroblastoma tumors where MYCN is amplified (4). Those findings, along with ours, suggest that (a) unknown mechanisms contribute to progression of neuroblastoma by causing genetic alterations, including MYCN amplification, as well as methylation-mediated inactivation of a subset of tumor suppressor genes; (b) methylation-mediated inactivation of a subset of tumor suppressor genes may cause genetic changes that lead to progression of neuroblastoma; or (c) MYCN amplification and/or other alterations in advanced neuroblastomas may bring about a CpG island methylator phenotype (3). Gonzalez-Gomez et al. (23) reported that higher aggressiveness, represented at the molecular level by concurrent MYCN amplification and 1p loss in neuroblastoma, was not paralleled by an accumulation of methylation events among various genes they examined, suggesting that CpG island methylation in advanced neuroblastoma could be specific to a subset of genes.

The NR1I2 gene encodes an orphan nuclear receptor that plays a key role in the regulation of xenobiotic response by controlling expression of drug metabolizing and clearance molecules (26–28). NR1I2 protein activates expression of genes encoding proteins such as CYP3A4 and ABCB1, which reduce the concentrations of xenocohens and toxic bile acids (29). However, effects of NR1I2 on cell growth or expression of growth-regulating genes have never been clarified, although we have shown here that the induction of ectopic NR1I2 inhibited growth of neuroblastoma cells. Other nonsteroidal nuclear receptors, such as all-trans retinoic acid receptor and vitamin D3 receptor, which form heterodimers with the 9-cis retinoic acid receptor in the same way as NR1I2, mediate antiproliferative and differentiation-promoting activities toward several malignant cell types (30, 31). Therefore, growth-suppressive activity might be one of the normal functions of NR1I2 although its mechanisms remain unknown.

To achieve some clarity with respect to the growth inhibitory activity of NR1I2, we tried to determine its putative transcriptional targets. Among 105 genes through an expression array analysis, we selected 10 genes for validation by semiquantitative PCR based on their possible cancer-associated function (Online Mendelian Inheritance in Man), and identified one candidate, PLA2G2A, encodes secretory phospholipase A2, as a possible target of NR1I2, although it will be needed to determine whether PLA2G2A is a direct or indirect target. This product qualifies as a tumor suppressor because mice lacking PLA2G2A expression show increased colonic polyposis (32). Interestingly, PLA2G2A was mapped to chromosome 1p36, a region frequently implicated in the pathogenesis of neuroblastoma (33). Further screening of possible targets of NR1I2 will be necessary to clarify how NR1I2 regulates neuroblastoma cell growth.

Because only 7 of 51 neuroblastoma patients in our study died during follow-up periods, we did not perform a survival analysis. However, the high prevalence of NR1I2 silencing through DNA methylation that we observed in aggressive neuroblastomas, along with the shown growth suppression activity of NR1I2, indicate that this molecule might serve as a diagnostic marker to predict prognosis.
