Prohibitin Is a Novel Target Gene of Vitamin D Involved in Its Antiproliferative Action in Breast Cancer Cells

Xinjian Peng, Rajeshwari Mehta, Sheng Wang, Srikumar Chellappan, and Rajendra G. Mehta

Abstract

Previously, we showed that N-methyl-N-nitrosourea–transformed MCF12F breast epithelial cells exhibited differential expression of several genes, including up-regulation of prohibitin and elevated sensitivity to a relatively noncalcemic vitamin D analogue, 1α-hydroxyvitamin D5 [1α(OH)D5]. In this report, we evaluated the functional significance of prohibitin in relation to the cellular response to vitamin D. The in silico screening for putative transcription factor binding sites identified two vitamin D receptor (VDR)/retinoid X receptor binding sites in the 1-kb promoter region of prohibitin. Prohibitin up-regulation by 1α(OH)D5 treatment at both transcriptional and translational levels was confirmed by real-time reverse transcription-PCR and Western blot analysis in breast cancer cells, identifying prohibitin as a vitamin D target gene. Conoc founders analysis showed that prohibitin was localized in the nuclei of MCF-7 cells and a portion of prohibitin was co-localized with VDR, but direct physical interaction between VDR and prohibitin in cell lysates was not detectable. In MCF-7 cells expressing tetracycline-inducible prohibitin (Tet-On model), the over-expression of prohibitin inhibited cell proliferation and enhanced vitamin D–induced antiproliferative activity. Knockdown of prohibitin was accompanied by increased number of cells incorporating bromodeoxyuridine in the whole population and increased cell distribution in the S phase of cell cycle. In addition, prohibitin level had no significant effect on the vitamin D–induced transactivation of CYP24, a VDR target gene. This is the first report to suggest that prohibitin serves as a novel vitamin D target gene, which is involved in the antiproliferative action of vitamin D without affecting CYP24 transactivation in breast cancer cells. (Cancer Res 2006; 66(14): 7361-9)

Introduction

It is now well recognized that the active metabolite of vitamin D plays a significant role as a modulator of cell proliferation and differentiation in addition to its principal function in bone mineralization. However, its clinical use in cancer prevention and therapy is hampered due to its toxic effects at efficacious concentrations. Therefore, considerable effort has been diverted toward designing and synthesizing chemical analogues of vitamin D that are less calcemic and more potent in inhibiting growth of cancer cells. We synthesized one such less calcemic analogue, 1α-hydroxy-24-ethyl-cholecalciferol [1α(OH)D5], which has shown promising chemopreventive effect in mouse mammary organ culture system (1, 2), chemically induced rat mammary carcinogenesis and breast cancer xenograft model using athymic mice (3, 4). To this end, 1α(OH)D5 is being developed for phase I clinical trials for breast cancer patients. Our previous effort to identify transformation-associated genes using microarray analysis found that several genes were up-regulated in carcinogen-transformed human breast epithelial cells compared with the untransformed cells (MCF12F), including prohibitin, TCTP1, and thioredoxin (3, 5). Because it is well known that vitamin D arrests epithelial cells in G1 phase of the cell cycle whereas prohibitin has been reported to have tumor-suppressive and antiproliferative effects, we selected prohibitin to determine if it has any functional significance in vitamin D action. The prohibitin gene encodes a protein of 275 amino acids with a molecular mass of 28 to 30 kDa. It is highly evolutionarily conserved and mapped to chromosome 17q12-21 (6). Its protein is localized into the inner membrane of the mitochondria, where it might have a role as a mitochondrial chaperon protein in a complex with BAP37 in the maintenance of mitochondrial function and protection against senescence (7–9). In addition, prohibitin also plays a regulatory role within the cell cycle, although the precise role of the protein in cell cycle regulation is not well understood (10). Earlier work considered prohibitin as a potential tumor suppressor gene because microinjection of prohibitin transcripts resulted in growth arrest in HeLa cells (11). Prohibitin has also been reported to be localized to the nuclei of breast cancer cells (12) and to mediate hormone response in prostate cancer and ovary granulosa cells (13, 14). There is evidence for the interaction of prohibitin with the cell cycle checkpoint molecules, including E2F (15), p53 (12), and pRB (16, 17), and the overexpression of prohibitin can modulate transcription of multiple genes in the transfection experiments. This suggests a potential mechanism of prohibitin function in cell cycle regulation (12, 15, 17). Recent reports indicate that prohibitin is up-regulated in tumor cells compared with normal cells (18–20). Moreover, it has been reported as one of the target genes for c-Myc (21, 22). The consistently higher levels of prohibitin in cancer cells may be due to the transactivation of c-Myc gene (8). Thus, it seems that prohibitin is involved in diverse cellular processes, including proliferation, stress (7), cell migration (23), etc., associated with its different localization in the cells; however, its nuclear function is still far from clear. Our attempt to characterize the role of prohibitin in vitamin D receptor (VDR) function led to the identification of prohibitin as a novel vitamin D target gene that is involved in the antiproliferative action of vitamin D without affecting CYP24 transactivation in breast cancer cells.
Materials and Methods

**Vitamin D analogue.** 1α(OH)D$_3$ was synthesized according to the procedure described previously (1). 1α(OH)D$_3$ was dissolved in ethanol, and the stock solution of 10 mmol/L 1α(OH)D$_3$ in ethanol was stored in −80°C freezer. The appropriate controls for each experiment consisted of treatment with the vehicle (ethanol) used at a concentration <0.01% of total cell culture medium. 1,25(OH)$_2$D$_3$ was purchased from Sigma-Aldrich Corp. (St. Louis, MO).

**Cell culture.** MCF-7, BT474, and MDA-MB231 cell lines were purchased from the American Type Culture Collection (Manassas, VA) and cultured as described previously (24). MCF-7 cells expressing tetracycline-inducible prohibitin (tagged by c-Myc) were grown in DMEM supplemented with 10% tetracycline-free fetal bovine serum (FBS; Clontech, Palo Alto, CA), 25 μg/mL Zeocin (Invitrogen, Carlsbad, CA), and 0.25 μg/mL Blasticidin (Invitrogen) as described (12). Prohibitin was induced by incubation of cells with 1 μg/mL tetracycline or 20 ng/mL doxycycline in the MCF-7 Tet-On model. A day before treatment, cells were seeded and incubated for 24 hours in growth medium to allow cells to attach and the serum in the medium was reduced to 5%. Then, cells were treated with 0.5 μmol/L 1α(OH)D$_3$ or 10 nmol/L 1,25(OH)$_2$D$_3$ for different times. For long treatments, medium was changed every other day.

**RNA extraction and real-time reverse transcription-PCR.** Total RNA extraction and reverse transcription reaction were done as described previously (24). RNA was further subjected to DNase I (Ambion, Austin, TX) digestion and purification using RNEasy Mini Kit (Qiagen, Valencia, CA) before reverse transcription. Real-time PCR was done with 1 μL reverse transcription product in a MyIQ real-time PCR detection system (Bio-Rad, Hercules, CA) by using iQ SYBR Green PCR Supermix (Bio-Rad) according to the manufacturer's guidelines. The PCR cycling conditions used were as follows: 40 cycles of 15 seconds at 95°C, 15 seconds at 60°C, and 20 seconds at 72°C. Fold inductions were calculated using the formula 2$^{-[(ΔΔCt)]}$, where ΔΔCt is ΔCt(treatment) − ΔCt(control), ΔCt is Ct(target gene) − Ct(Δinternal), and Ct is the cycle at which the threshold is crossed. The gene-specific primer pairs (and product size) for the gene analyzed here were as follows: prohibitin, 5′-ACCACTGATAGTGCCCGTCA-3′ (forward) and 5′-TAGTCTCCTCTCCTGCTGTC-3′ (reverse; 126 bp); CYP24, 5′-CTCACACAGCTGATGCAATT-3′ (forward) and 5′-ACTGTTTTGCTGCTGTGGTCC-3′ (reverse; 122 bp); and β-actin, 5′-CTCTTCCAGCTCTCC-3′ (forward) and 5′-AGCAGCTTGGTGGCTAC-3′ (reverse; 116 bp). PCR product quality was monitored using post-PCR melt curve analysis.

**Cell proliferation assay.** Cell proliferation was evaluated using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay, direct cell counting, and bromodeoxyuridine (BrdUrd) labeling to known mammalian genes. To knock down prohibitin by RNA interference, 105 cells per well were transfected with 0.5 μg/well pcDNA3.1 empty vector (control) or 0.3 μg/well pcDNA3.1PHB expression vector. After 5 hours of incubation, the medium was replaced with medium containing 10 mmol/L 1,25(OH)$_2$D$_3$ or ethanol (solvent control, 1 μL/10 mL medium), and cells were incubated for an additional 24 hours before analysis.

**RNA interference.** siRNA against prohibitin [prohibitin siRNA, 5′-CCCGAAAUACUCUGAGAAdTdT-T3′ (sense) and 5′-UUUCAGACUGAUUUCUGGG-dTdT-3′ (antisense)] was designed to target the 3′-untranslated region to 974 to 993 bp of sequence NM_002634 and synthesized by Integrated DNA Technologies, Inc. (Coralville, IA). Negative control siRNA [nonsilencing RNA, 5′-UUUCUCGGACGUGUCAGUdTdT-3′ (sense) and 5′-ACGGUGACAGUUGCGAGAdTdT-3′ (antisense); Qiagen] has no homology to known mammalian genes. To knock down prohibitin by RNA interference (RNAi), 10$^5$ cells per well were seeded in six-well plates in culture medium containing 5% FBS and incubated overnight. Prohibitin siRNA and nonsilencing siRNA were transfected using the RNAi Carrier kit (Epoch Bioslabs, Sugar Land, TX). Cells were first incubated with siRNA complex (siRNA at 80 nmol/L; siRNA to RNAi Carrier, 16) for 6 hours in Opti-MEM (Invitrogen) containing 2% FBS, and then FBS was increased to 5%. After overnight incubation, cells were incubated in fresh culture medium containing 5% FBS for 2 days, and then cells were subjected to BrdUrd incorporation assay or cell cycle analysis (25). Prohibitin knockdown was verified at the same time using reverse transcription-PCR (RT-PCR) and Western blot analysis.

**Results**

**Prohibitin is a vitamin D target gene.** Our earlier studies showed that prohibitin could be involved in cellular response to 1α(OH)D$_3$ in breast epithelial cells (5); therefore, a question was raised: is prohibitin a vitamin D target gene? To answer this
question, we first analyzed the promoter region of prohibitin to examine if potential VDR binding sites are present. As shown in Fig. 1A, the 1-kb 5′-flanking sequence (−1,000/+40) of prohibitin was analyzed with several transcription binding site identification programs, including MatInspector (26), Promo (27), TFSEARCH (http://www.cbrc.jp/research/db/TFSEARCH.html), etc. Both MatInspector (using Matrix Family Library version 6.0 with optimized similarity score set to be >0.75 for all vertebrates library) and Promo identified two potential DNA binding sites for VDR/retinoid X receptor (RXR) located at −958/−934 (core similarity, 0.785; matrix similarity, 0.796; positive strand) and −383/−359 (core similarity, 0.937; matrix similarity, 0.794; negative strand) of the 1-kb promoter sequence (Fig. 1A). In addition to the known binding sites, such as androgen receptor (13) and c-Myc (7), in the promoter region of prohibitin, MatInspector also identified multiple DNA binding sites for early growth response (EGR) in the promoter region of prohibitin, MatInspector also identified multiple DNA binding sites for early growth response (EGR) in the 1-kb promoter sequence (Fig. 1A).

MatInspector identified many promoter regions that show high identity to the authentic core and matrix sequences as identified by MatInspector version 2.2 and Promo. Nucleotides are numbered negatively to the left of the sequence with nucleotide +1 corresponding to the transcription start site. B, effects of 1α(OH)D₃ on the expression of prohibitin (PHB; top) and CYP24 (bottom) mRNA in BT474 breast cancer epithelial cells. BT474 cells were treated for 0, 2, 4, 8, 16, 20, and 24 hours with 0.5 μM 1α(OH)D₃. At each time point, RNA was extracted and analyzed by real-time RT-PCR. CYP24 mRNA expression was analyzed at the same time and served as a positive control for vitamin D response. The value at each time point represents the relative level of specific mRNA normalized to β-actin (the level of specific mRNA at time point 0 was set as 1). Points, mean of three independent experiments with duplicate analyses of each cDNA samples; bars, SE.

C, effects of 1α(OH)D₃ (0.5 μM/mL, 24 hours) on prohibitin expression in BT474 cells. Total proteins (40 μg) extracted from cells are loaded for Western blot analysis. 1α(OH)D₃ treatment significantly increased prohibitin expression. β-Actin was used as an internal control.

Prohibitin and Antiproliferative Action of Vitamin D

Figure 1. Prohibitin as a target gene of vitamin D. A, potential VDR/RXR binding sites in the promoter region of prohibitin gene. Underlined, core sequence (bold font) of the putative transcription binding sites for VDR/RXR and EGR (an identified VDR target gene) with high identity to the authentic core and matrix sequences as identified by MatInspector version 2.2 and Promo. Nucleotides are numbered negatively to the left of the sequence with nucleotide +1 corresponding to the transcription start site. B, effects of 1α(OH)D₃ on the expression of prohibitin (PHB; top) and CYP24 (bottom) mRNA in BT474 breast cancer epithelial cells. BT474 cells were treated for 0, 2, 4, 8, 16, 20, and 24 hours with 0.5 μM 1α(OH)D₃. At each time point, RNA was extracted and analyzed by real-time RT-PCR. CYP24 mRNA expression was analyzed at the same time and served as a positive control for vitamin D response. The value at each time point represents the relative level of specific mRNA normalized to β-actin (the level of specific mRNA at time point 0 was set as 1). Points, mean of three independent experiments with duplicate analyses of each cDNA samples; bars, SE. C, effects of 1α(OH)D₃ (0.5 μM/mL, 24 hours) on prohibitin expression in BT474 cells. Total proteins (40 μg) extracted from cells are loaded for Western blot analysis. 1α(OH)D₃ treatment significantly increased prohibitin expression. β-Actin was used as an internal control.

Basal transcriptional level of prohibitin correlates to cellular sensitivity to vitamin D in breast cancer cells. Because prohibitin is a vitamin D target gene and was reported to have antiproliferative effect, we next asked if basal level of prohibitin is associated with any cellular sensitivity to vitamin D. CYP24 transactivation and antiproliferative effect by vitamin D were used as two variables for evaluation. Three breast cancer cell lines (ER-negative MDA-MB231, ER-positive BT474, and MCF-7 cells) with different sensitivities were selected. As shown in Fig. 2A, MDA-MB231 has the lowest basal prohibitin expression level, whereas BT474 has the highest basal prohibitin expression level, 6-fold higher compared with that of MDA-MB231 cells; the basal prohibitin level in MCF-7 is 2-fold higher than that in MDA-MB231 cells. The basal prohibitin level correlates to cellular sensitivity in response to vitamin D in these cell lines (Fig. 2B and C): 1α(OH)D₃ at 0.5 μM/L dramatically induced CYP24 expression after 24-hour treatment and inhibited cell proliferation.

5 X. Peng and R.G. Mehta, unpublished data.

by 50% after 4-day treatment in BT474 cells. MCF-7 cells are responsive to 1α(OH)D₃ treatment but less sensitive compared with BT474 cells, whereas MDA-MB231 cells were resistant to 1α(OH)D₃ treatment. 1α(OH)D₃ failed to inhibit cell proliferation and only slightly induced CYP24 expression in MDA-MB231 cells. These data show that basal expression level of prohibitin could potentially contribute to cellular sensitivity to vitamin D in breast cancer cells.

Prohibitin is localized to the nuclei in MCF-7 breast cancer cells. We examined the distribution of prohibitin and VDR in MCF-7 cells by fluorescent immunostaining. MCF-7 cells are well...
characterized, express moderate level of prohibitin (Fig. 2A), and used for cell transfection studies in our laboratory. Confocal microscopic analysis showed that prohibitin was localized in the nuclei and a portion of prohibitin was colocalized with VDR (Fig. 3). Such nuclear accumulation of prohibitin has been previously reported (11–13, 16). The colocalization of prohibitin and VDR suggested that a potential physical association between the two molecules could exist and that prohibitin could regulate VDR-mediated cellular responses.

Characterization of prohibitin expression and its role in response to vitamin D in MCF-7 prohibitin Tet-On model. Because prohibitin is a target gene of vitamin D and a direct physical association between prohibitin and VDR may occur, we hypothesized that prohibitin expression plays a role in response to vitamin D. To test this hypothesis, a MCF-7 cell line expressing tetracycline-inducible c-Myc-tagged prohibitin (prohibitin Tet-On model; ref. 11) was used. Using this model, we evaluated the effect of prohibitin overexpression on vitamin D–induced cellular response. We first confirmed the increased expression of prohibitin with tetracycline (1 μg/mL) and its derivative doxycycline (50 ng/mL), the two Tet-system inducers. After 24 hours of treatment, both inducers effectively induced exogenous prohibitin expression. The c-Myc-tagged prohibitin was separated with a treatment, both inducers effectively induced exogenous prohibitin expression in MCF-7 cells using anti-c-Myc antibody (Fig. 4E). Results showed that doxycycline induced dose-dependent prohibitin expression with maximum induction at the concentration of 20 ng/mL. This concentration of doxycycline was therefore used for all the later experiments. Because the exogenous prohibitin is c-Myc tagged, we used anti-c-Myc antibody to confirm that the ~ 34-kDa protein band is in fact prohibitin by immunoblotting. As shown in Fig. 4C, the doxycycline-induced ~ 34 kDa protein band was also detected by anti-c-Myc antibody, whereas in Non-Tet-On MCF-7 cells doxycycline treatment did not induce prohibitin expression. As expected, reprobing the membrane with anti-prohibitin antibody revealed that all endogenous and exogenous prohibitin were detected and that the anti-prohibitin antibody was specific to prohibitin without cross-reaction with other proteins (Fig. 4D). These results once again confirm the nuclear localization of prohibitin shown in Fig. 3. To detect the possible physical interaction between prohibitin and VDR, coimmunoprecipitation was done using cell lysates made from cultured MCF-7 Tet-On cells. As shown in Fig. 4E, after immunoprecipitating proteins with polyclonal anti-VDR and monoclonal anti-c-Myc antibodies, the precipitated complexes were subjected to Western blot analysis using anti-prohibitin antibody (Fig. 4E). The proposed physical interaction between prohibitin and VDR was not detectable (Fig. 4E, lane 4), whereas c-Myc antibody precipitated exogenous c-Myc-tagged prohibitin from cell lysates (Fig. 4E, lane 6). However, reprobing the membrane with VDR antibody once again failed to detect physical interaction between prohibitin and VDR (data not shown). Interestingly, as shown in Fig. 4E (lane 6), in addition to exogenous c-Myc prohibitin band, endogenous prohibitin (28-30 kDa) as well as multiple protein bands at 90 to 130 kDa were detected by prohibitin antibodies from c-Myc antibody-precipitated complexes.

**Figure 4.** Characterization of prohibitin expression and cellular response to vitamin D in prohibitin Tet-On MCF-7 cell line. A, Western blot analysis of prohibitin expression in Tet-On MCF-7 cells expressing tetracycline-inducible c-Myc-tagged prohibitin. Both tetracycline (Tet; 1 μg/mL) and doxycycline (Dox; 50 ng/mL) induced exogenous prohibitin (~ 34 kDa) expression after 24 hours of treatment. B, optimization of doxycycline concentration in induction of prohibitin expression in Tet-On MCF-7 cells. Doxycycline (20 ng/mL) was determined to be the best concentration for this system. C and D, Western blot analyses of c-Myc-tagged prohibitin in Tet-On MCF-7 cells using anti-c-Myc (C) and anti-prohibitin (D) mAbs. Both antibodies specifically detect the exogenous prohibitin. E, immunoprecipitation (IP) of VDR (lane 4) and exogenous prohibitin (lane 6) from cell lysates made from MCF-7PHB Tet-On cells using anti-VDR polyclonal antibody (VDRPAb) and anti-c-Myc mAb. Prohibitin was not coprecipitated with VDR, but endogenous prohibitin was coprecipitated with exogenous c-Myc-tagged prohibitin (lane 6), indicating lack of physical interaction between VDR and prohibitin, and the formation of prohibitin homomers. Non-Tet-On MCF-7 cells (lane 7) served as a negative control for c-Myc-tagged exogenous prohibitin. F, inhibition of cell proliferation and enhancement of the antiproliferative effect of vitamin D in MCF-7 cells by prohibitin overexpression. Tet-On MCF-7 cells were incubated with either 10 nmol/L, 1.25(OH)2D3 (D3) or 0.5 μmol/L 1α(OH)D2 (D2) in the presence or absence of 20 ng/mL doxycycline for 4 days, and cell number was determined. Columns, mean of three independent experiments with triplicate wells in each experiment; bars, SE. *, P < 0.05, compared with the corresponding control [1.25(OH)2D3 versus control; 1α(OH)D2 versus control; doxycycline versus control; doxycycline + 1.25(OH)2D3 versus doxycycline or 1.25(OH)2D3 only; doxycycline + 1α(OH)D2 versus doxycycline or 1α(OH)D2 only], G, MCF-7 cells (Non-Tet-On) were grown in 12-well plates and treated with 10 nmol/L, 1.25(OH)2D3 in the presence or absence of doxycycline for 4 days. In Non-Tet-On MCF-7 cells, doxycycline at 20 ng/mL had very little effect on cell proliferation. **, P < 0.05, compared with the corresponding control [1.25(OH)2D3 versus control; doxycycline + 1.25(OH)2D3 versus doxycycline only].
The nature of the protein bands at 90 to 130 kDa is not clear at this time. Coimmunoprecipitation of endogenous prohibitin showed the formation of prohibitin homomers. This is consistent with the large prohibitin spots (possibly prohibitin homomers) observed in the nuclei in Fig. 3. To test the effect of prohibitin expression on vitamin D–induced cellular response, the MCF-7 cells expressing tetracycline-induced prohibitin were treated with 1α(OH)D₃ and 1,25(OH)₂D₃ in the presence and absence of doxycycline for 4 days and the cell number in each well was determined by direct counting (Fig. 4 F and G). Results showed that induction of prohibitin expression using doxycycline significantly inhibited cell proliferation, indicating that prohibitin itself has antiproliferative effect, which is supported by previous reports (11). Incubation of Tet-On MCF-7 cells for 4 days with 0.5 μmol/L 1α(OH)D₃ or 10 nmol/L 1,25(OH)₂D₃ effectively inhibited cell proliferation by ~27% in the absence of doxycycline, whereas vitamin D treatments in the presence of doxycycline (Tet-On, prohibitin is overexpressed) inhibited cell proliferation by ~50% in these cells. On the other hand, the incubation of Non-Tet-On MCF-7 cells with 1,25(OH)₂D₃ in the presence of doxycycline had no additive inhibitory effect on cell proliferation, indicating that the additive effect of vitamin D treatment is associated with the overexpression of prohibitin. These results support the notion that prohibitin is involved in the antiproliferative effect of vitamin D and at least partially contributes to cellular sensitivity to vitamin D.

Silencing of prohibitin using RNAi increased BrdUrd incorporation and cell distribution in S phase of cell cycle in MCF-7 cells. Given that prohibitin is a target gene of vitamin D and that it contributes to the antiproliferative action of vitamin D, we investigated the effect of knockdown of prohibitin by RNAi on cell proliferation in MCF-7 cells. Cell proliferation was evaluated by real-time RT-PCR (Fig. 5A) and was accompanied with decreased prohibitin protein expression by 80% as evaluated by Western blot analysis (Fig. 5B). BrdUrd incorporation assay using FACS analysis showed a significant increase (~3-fold) in BrdUrd-labeled cells after prohibitin knockdown (Fig. 5C and D) compared with nonsilencing control siRNA-transfected cells. Cell cycle analysis of prohibitin siRNA–transfected MCF-7 cells showed increased cell distribution in S phase and decreased cell distribution in G₁-G₀ phase of cell cycle (Table 1), confirming the results of BrdUrd incorporation assay after prohibitin is silenced by RNAi.

Prohibitin is not involved in CYP24 transactivation by vitamin D. Because prohibitin is involved in the antiproliferative action of vitamin D, we asked if prohibitin is involved in the CYP24 transactivation by vitamin D. CYP24 is an established direct target gene of VDR and is also a very sensitive marker for vitamin D response. We initially hypothesized that prohibitin expression affects the CYP24 transcription expression if a direct physical interaction between prohibitin and VDR was present, even if it was not detectable by coimmunoprecipitation. We did real-time RT-PCR analysis of CYP24 transactivation by vitamin D in the

PCR, but CYP24 transactivation by 1,25(OH)2D3 was not significantly affected, supporting the results obtained from MCF-7 cells. As shown in Fig. 6A, CYP24 transactivation induced by 1,25(OH)2D3 and 1α(OH)D3 (0.5 μmol/L; Fig. 6B), indicating that CYP24 transactivation by vitamin D in Tet-On MCF-7 cells and prohibitin siRNA–transfected MCF-7 cells was not affected by prohibitin expression level. To further confirm this, we also transiently transfected MDA-MB231 cells expressing low level of prohibitin (Fig. 2A) with prohibitin expression vector (pcDNA3.1PHB) to overexpress prohibitin in this cell line. After transfection, cells were treated with 1,25(OH)2D3 for 24 hours. As shown in Fig. 6C, transient transfection caused dramatic overexpression of prohibitin as evaluated by real-time RT-PCR, but CYP24 transactivation by 1,25(OH)2D3 was not significantly affected, supporting the results obtained from MCF-7 cells.

Discussion

VDR signaling pathway is fundamental to chemoprevention and therapy of breast cancer using vitamin D analogues. Although the antiproliferative effects of vitamin D in breast cancer cells are well recognized, the detailed signaling pathway and target genes involved in this process still need to be identified and characterized. In this study, we identified prohibitin as a novel target gene of VDR function, which is involved in the antiproliferative action of vitamin D.

Our initial in silico effort identified two potential VDR/RXR binding sites in the promoter region of prohibitin. Although whether VDR directly binds to the promoter of prohibitin still needs further experimental verification, our real-time RT-PCR and immunoblot analyses have confirmed that prohibitin is a primary vitamin D target gene. Many vitamin D target genes, including osteopontin, osteocalcin, calbindin, etc., which are classically involved in calcium homeostasis and bone metabolism, have been identified. In addition, a few cell cycle–regulated genes, such as p21 and cyclin C, are also known to be regulated by vitamin D and related to the antiproliferative action of vitamin D. The identification of prohibitin as a novel vitamin D target gene adds a new member to the list of vitamin D–responding genes related to cell cycle control. The transcriptional and translational regulation of prohibitin by vitamin D is very similar to that of cyclin C (30, 31) in breast cancer cells. Interestingly, at mRNA level, both prohibitin and cyclin C are quickly up-regulated after vitamin D treatment with peaks at 8 and 3 hours after treatment, respectively, followed by gradual reduction in expression, whereas CYP24 induction lasts for at least 24 hours. At peak mRNA levels, both prohibitin and cyclin C are ~2-fold of their basal levels (30), whereas at protein level both are >2-fold of their basal levels (31). Such quick, transient, and significant regulation of prohibitin by vitamin D might be a sign of tight control of the expression of this gene in response to vitamin D.

Prohibitin has multiple functions ranging from a role in aging (32), epithelial cell migration (23), mitochondrial inheritance (33), and as a chaperone for the stabilization of mitochondrial proteins in yeast (9) to its role in cell cycle control, apoptosis (12), and as associated molecules in cell surface receptors in mammalian cells (34, 35). Accumulative evidence shows its nuclear function in transcription regulation. Our data show that a portion of prohibitin colocalizes with VDR in the nuclei of MCF-7 cells, and it is involved in VDR-mediated antiproliferative action of vitamin D. Prohibitin was found to interact with multiple molecules in the cells, including Bap37, Rb, p53, E2F, cIaf1, α-actinin, and annexin A2 (36), and also form homomers with prohibitin itself (Fig. 4E). These
prohibitin can inhibit cell proliferation by directly interacting with other proteins, we initially proposed that prohibitin mediates vitamin D response on cell proliferation. If prohibitin physically binds to VDR, the interaction between the two molecules could be very low or they do not physically interact with each other in the cells. Later experiments on CYP24 transactivation by vitamin D further support this notion because CYP24 is a very sensitive marker in response to vitamin D and a direct target gene of VDR. If prohibitin physically binds to VDR, the expression level of prohibitin would affect CYP24 transactivation by vitamin D. However, the results indicated that prohibitin-mediated vitamin D response on cell proliferation was independent of CYP24 transactivation.

The detailed mechanism by which prohibitin can induce antiproliferative and cell cycle regulatory activity, although intriguing, is yet to be established. There is even considerable controversy about the function of prohibitin localized in the nuclei. Because emerging data show the diversified localization and translocation, it is not surprising to see that prohibitin is associated with multiple functions in the cells. It is believed that prohibitin can inhibit cell proliferation by directly interacting with both pRb and p53 pathways, suggesting a mechanism dependent of the pRb and p53 pathways is involved in the antiproliferative effects of prohibitin (10). Recent evidence has shown that prohibitin recruits Brg-1 and Brm to E2F-responsive promoters and that this recruitment is required for the repression of E2F-mediated transcription by prohibitin (35, 39). Brg-1 and Brm are involved in chromatin remodeling and mediating hormone-dependent transcriptional activation by nuclear receptors (10), which could provide a common explanation for the diverse effects of nuclear prohibitin in different cells. In breast cancer cells, the depletion of prohibitin by antisense or siRNA strategies inhibits the growth-inhibitory effect of the antiestrogen 4-hydroxytamoxifen and ICI 182,780. Moreover, the transfection of a construct expressing residues 304 to 357 of E2F, which inhibits the interaction between prohibitin and E2F, blocked the antiestrogenic effect, suggesting an important role of prohibitin in the antiproliferative actions of estrogen antagonists (39). Similar mechanism may also be involved in the antiproliferative action of vitamin D. In the present study, we observed that prohibitin is up-regulated by vitamin D treatment and its level correlates with the cellular sensitivity to vitamin D. Overexpression of prohibitin enhanced the antiproliferative effect of vitamin D in MCF-7 cells, whereas knockdown of prohibitin was associated with increased proliferating cells in the whole-cell population. These results identify prohibitin as one of the important molecules involved in the antiproliferative action of vitamin D. Similarly and in consistence with our studies, in androgen-stimulated LNCap prostate cancer cells, prohibitin is down-regulated (13). Interestingly, vitamin D3 and its analogue have been reported to suppress the androgen-stimulated growth of mouse mammary carcinoma SC-3 cells (40) and block in vitro and in vivo androgen-stimulated prostate cell growth (41).

Although prohibitin is involved in the antiproliferative action of vitamin D, it is not involved in the CYP24 transactivation by vitamin D, suggesting that vitamin D could use different VDR-mediated pathways for its antiproliferative effects and CYP24 activation, respectively. Previous studies have also reported that the growth-inhibitory pathway of 1,25(OH)2D3 could be selectively abrogated, whereas cells remained sensitive to direct 1,25(OH)2D3 signaling (induction of CYP24; ref. 42). A proposed interaction of prohibitin with VDR and other steroid receptors is diagrammatically shown in Fig. 7.

This is the first report to indicate that prohibitin is involved in the antiproliferative action of vitamin D. Our results, together with the findings of others for the role of prohibitin in the action of androgen (13) and estrogen antagonists (39), suggest that prohibitin may regulate the action of steroid hormones.
