Abstract

Despite recent improvements in therapeutic management of osteosarcoma, ongoing challenges in improving the response to chemotherapy warrants new strategies still needed to improve overall patient survival. In this study, we investigated in vivo the effects of RAD001 (Everolimus), a new orally available mTOR inhibitor, on the growth of human and mouse osteosarcoma cells either alone or in combination with zoledronate (ZOL), an antosteoporotic drug used to treat bone metastases. RAD001 inhibited osteosarcoma cell proliferation in a dose- and time-dependent manner with no modification of cell-cycle distribution. Combination with ZOL augmented this inhibition of cell proliferation, decreasing PI3K/mTOR signaling compared with single treatments. Notably, in contrast to RAD001, ZOL downregulated isoprenylated membrane-bound Ras concomitantly with an increase of nonisoprenylated cytosolic Ras in sensitive and resistant osteosarcoma cell lines to both drugs. Moreover, ZOL and RAD001 synergized to decrease Ras isoprenylation and GTP-bound Ras levels. Further, the drug combination reduced tumor development in two murine models of osteoblastic or osteolytic osteosarcoma. We found that ZOL could reverse RAD001 resistance in osteosarcoma, limiting osteosarcoma cell growth in combination with RAD001. Our findings rationalize further study of the applications of mTOR and mevalonate pathway inhibitors that can limit protein prenylation pathways. Cancer Res; 70(24); 10329–39. ©2010 AACR.

Introduction

Current therapeutic strategies of osteosarcoma are based on tumor resection associated with highly toxic chemotherapy and fail to improve prognosis (1, 2) due to an absence of response to antitumor drugs observed in many cases. Failure of anticancer therapies often occurs from innate or/and acquired drug resistances of tumor cells to chemotherapies (3). In this context, therapies based on combinatorial drug approaches (4) appear as adapted clinical strategies for improving therapy and overcoming the multifaceted characteristics of cancer cells.

Osteoclasts are the main target in bone of nitrogen-containing bisphosphonates (N-BP) including such as zoledronate (ZOL) on which they induce apoptosis by inhibiting enzymes of the mevalonate pathway (5–7). Thus, the most common clinical application is osteoporosis, but bisphosphonate application has been extended to the treatment of malignant hypercalcemia. In addition, recent in vitro studies demonstrated an antitumor activity exerted by ZOL on cancer cells (8–10). Result of in vivo experiments also highlighted the therapeutic interest of ZOL alone or in combination with conventional chemotherapy on the growth of carcinoma (11) and sarcoma (12).

mTOR plays a key role in regulating protein metabolism, and dysregulations in mTOR signaling are frequently associated with cancer progression (13). Indeed, mTOR is a member of the PI3K family such as ATM and ATR proteins associated with cancer progression (13). Indeed, mTORC-1 and mTORC-2, which are member of the PI3K family such as ATM and ATR proteins associated with cancer progression (13). Indeed, mTORC-1 and mTORC-2, which are

pediatrics tumors in vitro and in vivo including osteosarcoma (27, 28). In this context, a phase II clinical trial in patients with advanced soft tissue or bone sarcomas revealed that AP23573 exhibits single-agent activity in patients as shown by the prolonged overall survival (29) pointing out the pivotal role of the mTOR pathway in the pathogenesis of osteosarcoma. However, resistance to rapamycin has been identified and was associated with a decreased binding to it, altered mTOR up- or downstream signaling or feedback loop associated with mTOR pathway (30).

Because RAD001 appears to be a promising agent for the treatment of neoplastic diseases, the effects of RAD001 was investigated on the growth of osteosarcoma cells, both alone and in combination with ZOL. We also investigated the mechanisms involved in the RAD001 sensitivity and resistance of osteosarcoma cells and assessed a method to abolish RAD001 resistance in vitro and in vivo.

Materials and Methods

The rat osteosarcoma OSRGA cell line established from a radio-induced osteosarcoma (31) and human MG63 cells purchased from ATCC (Promochem) were cultured in DMEM (Lonza) supplemented with 10% fetal calf serum (FCS; Hyclone). Murine osteosarcoma POS-1 and MOS-J cells derived from mouse spontaneous osteosarcoma were provided, respectively, by Drs. Kamijo (32) and Shultz (33) and were cultured in RPMI with 10% FCS. Cells expressed osteoblastic markers, more specifically cbfa1/Runx2 and bone alkaline phosphatase (data not shown), and MOS-J cells were able to form mineralized nodules in vitro (33). These parameters were tested before cell implantation.

Cell growth and viability

Cell growth and viability were determined by XTT reagent assay kit (Roche Molecular Biomedicals). Two thousand cells were cultured for 72 hours in the presence or absence of RAD001 (0.1–100 nmol/L), ZOL (0.1–100 μmol/L), or in combination of 1 or 10 nmol/L RAD001 with 1 μmol/L ZOL. ZOL and RAD001 were provided by Pharma Novartis AG. Similar experiments were performed in the presence or absence of clodronate (100–300 μmol/L; Sigma), Risodronate (2–100 μmol/L; Procter&Gamble), or Manumycin A (2 or 3 μmol/L; Sigma) combined or not with 1 nmol/L RAD001. After the culture period and addition of XTT reagent, the absorbance was then determined at 490 nm. Cell viability was also assessed by Trypan blue exclusion; viable and nonviable cells were manually counted.

Caspase activity

Twenty thousand cells were treated for 72 hours with or without RAD001 (0.1–100 nmol/L), ZOL (0.1–100 μmol/L) or a combination of 1 or 10 nmol/L RAD001 with 1 μmol/L ZOL. Caspase-3 activity was assessed on 10 μL of total cell lysates using the kit CaspACE Assay System (Promega), following the manufacturer’s recommendations. Results were expressed in arbitrary units and corrected for protein content quantified using the BCA test (Pierce Chemical Co.). Cells treated with 100 nmol/L Staurosporin for 24 hours were used as a positive control.

Time-lapse microscopy

Cells were cultured at 5 × 10^5 cells/mm² in the presence or absence of 10 nmol/L RAD001. Time-lapse experiments were started just after adding the pharmaceutical agent. Phase-contrast photos were taken every 10 minutes for 72 hours through a Leica DMI 6000B microscope using ×10 objective. Cell divisions in each field of observation were then manually scored in a time-dependent manner. Each condition was performed in duplicate.

Cell-cycle analysis

Subconfluent OSRGA, MG63, POS-1, or MOS-J cells were incubated with or without 1 μmol/L ZOL and/or 1 to 10 nmol/L of RAD001 for 24 to 72 hours. After the treatment period, trypsinized cells were incubated in PBS containing 0.12% Triton X-100, 0.12 mmol/L EDTA, and 100 μg/mL DNPase-free RNase A (Sigma). Then, 50 μg/mL propidium iodide were added for 20 minutes at 4°C in the dark. Cell-cycle distribution was studied by flow cytometry (Cytomics FC500, Beckman Coulter) on the basis 2N and 4N DNA content, and analyzed by DNA Cell Cycle Analysis Software (Phoenix Flow System).

Cell signaling analysis

Two hundred thousand cells were treated with 1 μmol/L ZOL or and 1 to 10 nmol/L RAD001 for 72 hours and then lysed in radioimmunoprecipitation (RIPA) buffer (150 mmol/L NaCl, 5% Tris, pH 7.4, 1% NP-40, 0.25% sodium deoxycholate, 1mmol/L Na3VO4, 0.5 mmol/L PMSE, 10 mg/mL leupeptin, 10 mg/mL aprotinin). Lysates were cleared of debris by centrifugation at 12,000 × g for 15 minutes. Total cell lysate (20 μg), determined by the BCA kit, was run on 10% SDS-PAGE and electrophoretically transferred to Immobilon-P membranes (Millipore). The membrane was blocked with antibodies to p-mTOR, p-p70S6K, p-4E-BP1, p-4EKT, p-Pi3K, p-PTEN, actin (Supplementary Table 1) in PBS, 0.05% Tween 20, and 3% bovine serum albumin. Similarly, an unprenylated form of Rap1A was detected by Western blot to indirectly quantify farnesyl diphosphate synthase (FPPS) activity (10). The membrane was washed and probed with the secondary antibody that was coupled to horseradish peroxidase. Antibody binding was visualized with the enhanced chemiluminescence system (Roche Molecular Biomedicals). For quantification, the emitted glow was acquired with a CCD camera and analyzed with the GeneTools program (Syngene).

Ras isoprenylation and GTP-binding activity

To measure isoprenylated membrane-bound Ras and non-isoprenylated cytosolic Ras, cells were lysed in 1 mL of lysis buffer (50 mmol/L HEPES; 750 mmol/L KC1; 200 mmol/L sucrose; 10 mmol/L NaHCO3, pH 7.4), supplemented with protease inhibitor cocktail set III (100 mmol/L AEBSF, 80 mmol/L aprotinin, 5 mmol/L bestatin, 1.5 mmol/L E-64, 2 mmol/L leupeptin, and 1 mmol/L pepstatin; Calbiochem), 1 mmol/L Na3VO4, 1 mmol/L NaF, 1 mmol/L I-(2-aminoethyl) benzenesulfonyl fluoride (AEBSF), 10 mmol/L aprotinin and

Cancer Res; 70(24) December 15, 2010
Cancer Research
10 mmol/L dithiothreitol), then sonicated (Labsonic sonicator) and centrifuged at 13,000 × g for 5 minutes at 4°C. Supernatants were collected and centrifuged at 100,000 × g for 1 hour at 4°C; the cytostatic fraction in the new supernatant was collected, whereas the pellets (membrane fraction) were resuspended in 100 μL of lysis buffer. Cytostatic fraction (30 μg) and membrane fraction (60 μg) were subjected to 15% SDS-PAGE and Western blot analysis, using an anti-Ras antibody (Supplementary data 1). The Ras-GTP binding assay was performed as previously described (34). Briefly, cells were lysed in MLB buffer (125 mmol/L Tris-HCl, pH 7.4, 750 mmol/L NaCl, 1% NP40, 10% glycerol, 50 mmol/L MgCl2, 5 mmol/L EDTA, 25 mmol/L NaF, 1 mmol/L NaVO4, 10 μg/mL leupeptin, 10 μg/mL pepstatin, 10 μg/mL aprotinin and 1 mmol/L PMSF) and centrifuged at 13,000 × g for 10 minutes at 4°C. An aliquot of supernatant was taken out for determination of protein content (BCA kit). Cell lysate (30 μg) was incubated for 45 minutes at 4°C with the Ras Assay Reagent (Raf-1 RBD, GST-tagged Agarose beads; Millipore), then the beads were washed and resuspended in 20 μL Laemmli buffer (125 mmol/L Tris, 4% w/v SDS, 20% v/v glycerol, and 1% β-mercaptoethanol). The amount of active GTP-bound Ras was detected by SDS-PAGE and Western blotting as reported earlier.

In vivo experiments

Mice (Elevages Janvier) were housed under pathogen-free conditions at the Experimental Therapy Unit (Faculty of Medicine, Nantes) in accordance with the institutional guidelines of the French Ethical Committee and under the supervision of authorized investigators.

Osteoblastic osteosarcoma model. Four-week-old male C57BL/6j mice were anesthetized by inhalation of a combination of isoflurane/air associated with an intramuscular injection of Buprenorphine (Temgesic, Schering-Plough) before intramuscular injection of 2 × 105 MOS-J cells. Tumors appeared in contact with the tibia approximately 8 days later and lead to osteoblastic lesions reproducing the osteoblastic form of human osteosarcoma (33).

Osteolytic osteosarcoma model. Four-week-old male C3H/He mice were anesthetized as previously described before subcutaneous inoculation of POS-1 cell suspension (containing 2 × 106 cells) in the hind footpad of the mice. Under these conditions, mice develop a primary tumor at the site of injection in 3 weeks that can be transplanted to mice of the same strain as a small fragment (2 × 2 × 2 mm3) in close contact with the tibia. For this purpose, the periosteum of the diaphysis was opened and resected along a length of 5 mm, and the underlying bone was intact. The osteosarcoma fragment was placed contiguous to the exposed bone surface without the periostium, and the cutaneous and muscular wounds were sutured. Tumors appeared at the graft site approximately 8 days later associated with the development of pulmonary metastases in a 3-week period. The tumors that develop in contact to the femora lead to osteolytic lesions that reproduce the osteolytic form of human osteosarcoma (35).

For both models, the tumor volumes (V) were calculated from the measurement of 2 perpendicular diameters using a caliper according to the following formula: V = 0.5 × L × S², where L and S represent the largest and smallest perpendicular tumor diameters, respectively. Four groups of 8 mice each were assigned as controls (placebo by oral administration and PBS injection subcutaneously twice a week), RAD001 (5 mg/kg, oral administration, twice a week), ZOL (100 μg/kg, subcutaneously, twice a week) and RAD001 + ZOL (combined treatment with subcutaneous 100 μg/kg ZOL and 5 mg/kg RAD001 oral administration, twice weekly) groups. The treatment started 1 day after tumor cell implantation. Treatment continued until each animal showed signs of morbidity including cachexia or respiratory distress, at which point they were sacrificed by cervical dislocation. Analysis of architectural parameters was done using high-resolution X-ray micro–computed tomography (CT; SkyScan-1072). Relative volume (BV/TV) of the tibia [total bone (cortical + trabecular) or trabecular bone] was quantified at necropsy on a 6.4-cm-length area located between superior metaphysis and diaphysis. Radiographs were taken at the same time (PLANMED Sophie apparatus). Each experiment was repeated twice and only 1 set of experiments was shown.

Statistical analysis

Each experiment was repeated independently 3 times. The mean ± SD was calculated for all conditions and compared by ANOVA followed by Bonferroni post hoc test. Differences relative to a probability of 2-tailed P < 0.05 were considered significant.

Results

RAD001 exerts a cytostatic activity on osteosarcoma cells and synergizes with N-BP in vitro

RAD001 significantly reduced MG63, OSRGA, and POS-1 osteosarcoma cell number in a dose-dependent manner (P < 0.01; C50: 0.5 mmol/L, 1.26 mmol/L, and 45 mmol/L for OSRGA, MG63, and POS-1 cells, respectively) with a maximum effect at 100 mmol/L (concentrations tested up to 1 μmol/L; Fig. 1A). ZOL strongly diminished the number of MG63, OSRGA, and POS-1 cells assessed in a dose-dependent manner (Fig. 1B). Manual counting of viable cells did not evidence cell death in any condition tested, as confirmed by the absence of caspase activity in (data not shown). Time-lapse microscopy revealed that 10 mmol/L RAD001 clearly induced a marked decrease of mitoses in MG63, OSRGA, and POS-1 osteosarcoma cells detectable at early times of the treatment (6–11 hours; Fig. 1C). Moreover, osteosarcoma cells treated with RAD001 were not blocked in any phase of the cell cycle, but the cancer cells passed through the different phases at a slightly inferior rate than the untreated control (data not shown). These data demonstrate that RAD001, therefore, can be considered a cytostatic drug for osteosarcoma.

Figure 2 clearly shows a significant additive effect between RAD001 and ZOL for MG63, OSRGA, and POS-1 cells (Fig. 2A; P < 0.001). In contrast to the combination RAD001 and risedronate (another N-BP), which induced similar combinatory effect on cell proliferation (Fig. 2B, P < 0.001), clodronate (a non–N-BP, 100–500 μmol/L) did not significantly modulate RAD001 activity. This combinatory effect between RAD001 and ZOL was confirmed by Western blot.
In contrast to treatment with 1 nmol/L RAD001, which had no effect on the mTOR signaling pathway in POS-1 and OSRGA cells, as revealed by a decrease of mTOR phosphorylation, but not in MG63 osteosarcoma cells (Fig. 2C). ZOL (1 µmol/L) did not affect mTOR signaling (Fig. 2C). Interestingly, the combination of 10 nmol/L RAD001 and 1 µmol/L ZOL totally abolished P-mTOR and drastically inhibited its main downstream signaling partners, demonstrating a cross talk between ZOL and mTOR signaling pathways in all MG63, OSRGA, and POS-1 cells (Fig. 2B). Treatment of cells with 1 µmol/L ZOL did not alter unRAP1A expression, as did treatment with higher doses (data not shown, 10). Furthermore, the combination of RAD001 with ZOL strongly reduced P-PI3K, downregulated the phosphorylation of PTEN in MG63, OSRGA, and POS-1 cells (Fig. 2C). Consequently, this combination dysregulated the mTOR downstream signaling and decreased the phosphorylation of 4EBP1 in the 3 cell lines assessed (Fig. 2C). p70S6K was decreased in MG63 and OSRGA and slightly in POS-1 cells (Fig. 2C).

**Combined treatment with RAD001 and ZOL is efficient on RAD001-resistant osteosarcoma cells in vitro**

Mouse osteosarcoma MOS-J is totally refractory to RAD001 (up to 1 µmol/L tested) and ZOL (up to 10 µmol/L, 100 µmol/L being cytotoxic; Fig. 3A). Interestingly, combination of RAD and ZOL at low doses induced a synergistic antiproliferative effect on MOS-J cells (Fig. 3B, **P < 0.001**). The biological activity of RAD001 in MOS-J cells was demonstrated by Western blot analyses. Indeed, 10 nmol/L RAD001 decreased the phosphorylation of PI3K, PTEN, Akt, mTOR, P-4EBP1, and P-p70S6K (Fig. 3C) without any effect on MOS-J cell proliferation (Fig. 3B). Although ZOL alone did not also modulate these activities, ZOL and RAD001 exert an additive effect to strongly inhibit mTOR signaling (Fig. 3C).

**Ras-prenylation is strongly decreased by the combined treatment with RAD001 and ZOL.**

Ras is located at the crossroads between ZOL and mTOR signaling pathways. Indeed, ZOL is a powerful inhibitor of FPPS activity implicated in the prenylation of small GTPases (7, 13), and the PI3K/mTOR pathway belongs to the downstream cascades of Ras activation. In this context, we first analyzed the effects of the ZOL and RAD001 combination on Ras isoprenylation (Fig. 4). ZOL (1 µmol/L) induced a significant decrease of isoprenylated membrane-bound Ras and a concomitant increase of nonisoprenylated cytosolic Ras in all osteosarcoma cell lines tested, in contrast to 1 or 10 nmol/L RAD001, which had no effect on Ras isoprenylation (Fig. 4A). Although ZOL alone did not also modulate these activities, ZOL and RAD001 exert an additive effect to strongly inhibit mTOR signaling (Fig. 3C).
inhibitor of Ras farnesylation, was assessed on osteosarcoma cell proliferation in combination with RAD001 (Fig. 4B). In all osteosarcoma cell lines tested (sensitive and resistant to RAD001), Manumycin A and RAD001 exert an additive effect in inhibiting cell proliferation, thus mimicking ZOL activity (Fig. 4B, \( P < 0.001 \)).

The combination of RAD001 and ZOL reduces the growth of osteosarcoma cells in syngeneic murine models

Preliminary dose–response experiments were carried out in vivo to determine the sub-optimal efficient doses of RAD001 and ZOL (data not shown). The ZOL dose (100 \( \mu \)g/kg ZOL as research grade disodium salt) used in this study is equivalent to the intravenous clinical dose of 4 mg every 3 to 4 weeks. However, even if dosing frequency of twice a week is greater, these doses are justified by the very aggressive nature of the osteosarcoma models used and the short animal survival. Both drugs did not exert any side effects on animal body weight loss or any toxic effects in MOS-J and POS-1 osteosarcoma models.

The in vivo effects of single or combinatory treatment on tumor growth were first studied in a MOS-J osteosarcoma model, cells that are resistant to both agents in vitro. Doses of 5 mg/kg RAD001 or 100 \( \mu \)g/kg ZOL were chosen for the subsequent combination experiments because they had no significant effect alone on tumor growth, as compared with the control group (Fig. 5A and B). RAD001 and ZOL combination reduced the tumor volume compared with single treatment...
The relative tumor progression calculated between day 19 and day 31 confirmed the synergistic action between RAD001 and ZOL (Fig. 5B). Interestingly, combined treatment of RAD001 and ZOL significantly slowed down the tumor progression compared with a single treatment and to the control group (Fig. 5B). Furthermore, radiographs revealed that 100 mg/kg ZOL strongly reduced bone degradation (Fig. 5C) even if it had no effect on the tumor progression (Fig. 5A, Fig. 5B). Indeed, the metaphyses of long bones exhibited high bone density reflecting inhibition of bone resorption and retention of the primary spongiosa in contrast to 5 mg/kg RAD001, which had no protective effect of bone loss (Fig. 5C). The combination of RAD001 with ZOL had no additive inhibitory effect of bone resorption as compared with ZOL alone. By combining micro-CT image registration, the bone remodeling associated with osteosarcoma development has been followed and confirmed the radiographic analysis (Fig. 5D). ZOL (100 µg/kg) and 100 µg/kg ZOL + 5 mg/kg RAD001 significantly increased bone mass in contrast to 5 mg/kg RAD001 alone. This was confirmed by the quantification of relative bone volume (BV/TV). Indeed, BV/TV increased by approximately 40% in the presence of ZOL and ZOL + RAD001 compared with the control group (Fig. 5D, P < 0.001). RAD001 and ZOL induce additive effects on tumor development and reduce the growth of resistant MOS-J osteoblastic osteosarcoma cells in syngeneic mice. Histologic analyses demonstrated that the residual bone mass of animals treated with the combination of 100 µg/kg of ZOL and 5 mg/kg RAD001 was mainly composed of an extensive fibrosis associated with nontumorigenic cells and with extensive necrotic foci compared with the other groups (Supplementary Figure 3). These nontumorigenic cells, which were nonresponding cells to the treatment used and the necrotic tissue, did not allow a complete in vivo analysis of the phosphorylation status of mTOR pharmacodynamic markers such as p70S6K and 4EBP1.

Similar experiments were carried out using an osteolytic-POS-1 osteosarcoma model (35). RAD001 (5 mg/kg) had no effect on POS-1 tumor growth compared with the control group (Fig. 6B). ZOL slightly but not significantly reduced the tumor volume (Fig. 6A, Fig. 5B) but markedly decreased bone degradation as shown by an increase of bone mineral density of the metaphysis (Fig. 6C). On the contrary, 5 mg/kg RAD001 alone had no effect on tumor-induced osteolysis, and the combination of RAD001 with ZOL had no additive inhibitory effect of bone resorption as compared with ZOL alone (Fig. 6C). Interestingly, RAD001 and ZOL in combination significantly decreased the tumor volume compared with the control, and with single treatments (Fig. 6A). Such combination treatment slowed down the tumor progression (Fig. 6B, P < 0.001). Micro-CT analysis confirmed the significant impact of ZOL on osteolysis with an increase in BV/TV (Fig. 6D). The combinatory treatment clearly improved...
the quality of bone tissue compared with the control group and the single treatments (Fig. 6D).

Discussion

The absence of response of patients suffering from osteosarcoma to chemotherapy and the lack of effectiveness of single-drug therapy led to the development of new therapeutic approaches. Indeed, therapy based on combinatorial drug regimens targeting different metabolic pathways would prevent the emergence of resistance phenomena and increase the effectiveness of treatment while reducing toxicity for patients (36). Dysregulation of the PI3K/mTOR pathway, mainly due to redundant autocrine pathways rather than mutations, is clearly involved in the pathogenesis of sarcomas. mTOR is a central crossroads of many signaling pathways induced by growth factors and nutritional status, and this crossroad is deregulated in numerous cancer cells (36). It directly and indirectly controls many cellular events such as translation, transcription and protein stability, and regulates cell growth, proliferation, survival, and cell size (37). In this context, its functions have positioned mTOR as a potential target for cancer therapy and have stimulated the development of selective inhibitors of mTOR complexes (13). mTOR inhibitors have been already assessed in numerous malignancies (20) but only few data have been published on osteosarcoma.

The present work demonstrates the therapeutic interest of a rapamycin analogue, RAD001. RAD001 slowed down cell-cycle phases in all osteosarcoma cell lines studied, but in absence of a cell-cycle arrest or increase of cell death, this
effect may be explained by the role exerted by mTOR on protein synthesis. Indeed, protein synthesis is regulated by mTOR complex 1 (composed by mTOR, regulatory associated protein of mTOR, and G-protein subunit-like), which phosphorylates several substrates including ribosomal S6 kinase (S6K) and the eukaryote initiation factor 4E binding protein-1 (4EBP-1; ref. 38). Once activated, S6K phosphorylates the ribosomal protein S6, resulting in the translation of a subset of mRNAs encoding for essential ribosome proteins, including eukaryotic initiation factor-4B and increasing translation mechanisms. Similar to other immunosuppressive and chemotherapeutic agents, adverse events related to RAD001 are frequent and lead to moderate dropout rates (39). Interestingly, the combination of RAD001 and ZOL clearly synergized to slow down cell proliferation in all osteosarcoma cells studied, with a marked downregulation of mTOR, 4EBP1, and p70S6K phosphorylation. Thus, this combination may be used to limit the side effects of high drug doses. mTOR signaling is controlled by an upstream signal including PI3K, Akt activation (directly on mTOR or indirectly via TSC1/TSC2 complex) and complex feedback inhibitions. Such feedback loops could explain that mTOR inhibition induces upstream receptor tyrosine kinase signaling activating Akt as observed in human breast and prostate carcinoma cells (40), and in OSRGA and MG63 osteosarcoma cells.

Unfortunately, resistance phenomena to rapamycin have been described (41). This is the case for mouse osteosarcoma cells used in this study, which are resistant to RAD001 and rapamycin (data not shown).

In vitro experiments point out the additive effect between ZOL and RAD001 as revealed by the downregulation of mTOR downstream signaling (4EBP1, p70S6K) in RAD001-sensitive and -resistant osteosarcoma cells. ZOL strongly affects the mechanism of prenylation of small GTPases leading to its inhibition (refs. 7, 13; Fig. 7). Indeed, farnesyl diphosphate and geranylgeranyl diphosphate are required for the posttranslational lipid modification (prenylation) of small GTPases (i.e., Ras, Rho, and Rac). Among small GTPases, Ras activates the PI3K/mTOR cascade and like mTOR, it plays a central role in the regulation of various cellular processes. However, Ras bound to GTP is able to interact strongly with PI3K (42, 43). In the present work, low doses of ZOL alone or combined with

**Figure 5.** Effect of combinatory treatment of RAD001 with ZOL on the growth of resistant MOS-J osteosarcoma cells in syngeneic mice. Mice bearing MOS-J tumors (n = 8 per group) were assigned as CT (vehicle), RAD001 (5 mg/kg, twice weekly), ZOL (100 µg/kg, twice a week), or RAD001 + ZOL groups. A, the treatment started 1 day after tumor cell implantation (arrow). Evolution of tumors volumes (V). B, follow-up of tumor progressions. *, P < 0.05; ***, P < 0.001. C, radiographs taken at the time of sacrifice. D, micro-CT analyses performed on bones explanted. BV, bone volume; TV, total volume.
RAD001 decreased the isoprenylated-membrane bound form of Ras and increased the nonisoprenylated cytosolic Ras leading to the decrease of Ras bound to GTP and to the inhibition of the PI3K/mTOR signaling pathway. These data were confirmed by the use of manumycin A, which mimicked ZOL activity, clearly evidencing the involvement of Ras (Fig. 7). However, if Ras is potentially involved in the additive activity between ZOL and RAD001, the alterations of other prenylated proteins can be excluded.

The additive effect of ZOL and RAD001 was confirmed in 2 different murine osteosarcoma models. Combination of ZOL with RAD001 resulted in a significant downregulation of tumor progression associated with an increase of bone mass. However, no additive effect on bone the inhibition of bone resorption was evident in histomorphometric analysis confirming that ZOL potentiates RAD001 activity and not the contrary, ZOL also contributed to the decrease of tumor mass by inhibiting osteolysis. The interactions between tumor cells, tumor factors and the bone marrow microenvironment are crucial for the initiation and promotion of skeletal malignancies. These observations suggest a vicious cycle driving the formation of osteolytic bone tumors: tumor cells secrete soluble factors in bone (such as hormones, cytokines, and growth factors), which stimulate osteoclastic bone resorption through indirect RANKL production by osteoblastic stromal cells (44). The osteosarcoma models used in the present work are very aggressive and did not allow the investigation of curative treatments using critical tumor volumes. Indeed, at the critical tumor size approximately 200 to 300 mm³, the bone erosion has been already set up especially for the POS-1 model and the therapeutic benefit could not be gained by starting the treatment later. In this context, the combined treatment with ZOL and RAD001 appears potentially interesting for patients who have been diagnosed at early stages of their disease.

Overall, these data provide new insights in the molecular cross talk between mTOR and the mevalonate pathway and underline the therapeutic interest of multidrug treatment combining nitrogen bisphosphonate and mTOR inhibitors in osteosarcoma. The significance of this combination opens new areas in the field of therapeutic multidrug strategies for the treatment of primary bone tumors, especially in osteosarcoma.

Figure 6. ZOL and RAD001 induce additive inhibition of tumor growth in osteolytic POS-1 osteosarcoma model. Mice bearing POS-1 tumors (n = 8 per group) were assigned as CT (vehicle), RAD001 (5 mg/kg, twice weekly), ZOL (100 µg/kg, twice weekly), or RAD001 + ZOL groups. A, the treatment started 1 day after tumor cell implantation (arrow). B, follow-up of tumor progressions. ***, P < 0.001. C, radiographs taken at the time of sacrifice. D, micro-CT analyses performed on explanted bones. BV, bone volume; TV, total volume.
Disclosure of Potential Conflicts of Interest

No potential conflicts of interest were disclosed.

Grant Support

This work was supported by a grant from Pharma Novartis (Rueil-Malmaison, France) and by a NIH Cancer Core grant CA34196.
