Cooperation and Antagonism among Cancer Genes: The Renal Cancer Paradigm

Samuel Peña-Llopis1,2,3, Alana Christie3, Xian-Jin Xie3, and James Brugarolas1,2,3

Abstract

It is poorly understood how driver mutations in cancer genes work together to promote tumor development. Renal cell carcinoma (RCC) offers a unique opportunity to study complex relationships among cancer genes. The four most commonly mutated genes in RCC of clear-cell type (the most common type) are two-hit tumor suppressor genes, and they cluster in a 43-Mb region on chromosome 3p that is deleted in approximately 90% of tumors: VHL (mutated in ~80%), PBRM1 (~50%), BAP1 (~15%), and SETD2 (~15%). Meta-analyses that we conducted show that mutations in PBRM1 and SETD2 co-occur in tumors at a frequency higher than expected by chance alone, indicating that these mutations may cooperate in tumorigenesis. In contrast, consistent with our previous results, mutations in PBRM1 and BAP1 tend to be mutually exclusive. Mutation exclusivity analyses (often confounded by lack of statistical power) raise the possibility of functional redundancy. However, mutation exclusivity may indicate negative genetic interactions, as proposed herein for PBRM1 and BAP1, and mutations in these genes define RCC with different pathologic features, gene expression profiles, and outcomes. Negative genetic interactions among cancer genes point toward broader context dependencies of cancer gene action beyond tissue dependencies. An enhanced understanding of cancer gene dependencies may help to unravel vulnerabilities that can be exploited therapeutically. Cancer Res; 73(14); 4173–9. ©2013 AACR.
tumor cells in a sample. The prevalence of a mutation can be estimated by the mutant allele ratio (MAR), the fraction of the mutant over the mutant plus wild-type sequences for a given mutation (8). A heterozygous mutation would be expected to have a MAR of 0.5. Lower MARs may indicate that the mutation is present in only a subset of tumor cells in a sample (not a ubiquitous mutation), but this assessment is precluded by stromal contamination (8). Mutation sensitivity and MAR accuracy can be improved by the analysis of tumorigrafts, human tumors implanted in mice (8). In tumorigrafts, the stroma is replaced by the host and tumorigrafts preserve the characteristics of human tumors (9). However, studies in tumorigrafts rely on the ability to specifically query the human genome. Despite this limitation, MAR analyses in tumorigrafts can be instrumental to determine the prevalence of a mutation in a sample. Accurate MARs are helpful in a variety of other contexts. When mutations are found in areas of copy neutral LOH, MARs can show whether the mutation is homozygous (8). In addition, for mutations in areas of amplification, whether the mutant or the wild-type sequence is amplified can be determined with accurate MARs (8).

A comprehensive list of mutations in a tumor, together with an understanding of their prevalence and functional significance, should pave the way for better analyses of genetic interactions among cancer genes.

Evaluating Functional Relationships among Cancer Genes

Unraveling relationships among genes driving tumorigenesis is a challenge and represents the next frontier. A form of genetic interaction commonly reported is mutation exclusivity. Exclusivity is predicated of genes that are mutated in a particular tumor type, but not simultaneously. Often, mutation exclusivity is interpreted as evidence of functional redundancy. This is illustrated, for instance, by mutations in p16, D-type cyclins, CDK4, and retinoblastoma, which tend to be exclusive and disrupt the same cell-cycle regulatory pathway.

Mutation exclusivity is frequently misinterpreted owing to insufficient statistical power. As an example, when two genes are mutated at a frequency of 5%, the number of tumors required to show that a lack of mutation co-occurrence is due to a genetic interaction (as opposed to chance alone, after all, each gene is mutated in only 5% of the tumors) is 1,330. Thus, mutation exclusivity analyses may require meta-analyses of multiple studies, particularly when the interactions involve genes mutated at low frequencies.

Mutations and physical location

Another level of complexity is introduced by the physical location of cancer genes in chromosomes. In fact, the architecture of amplifications and deletions in tumors may be far more informative than previously appreciated. Traditionally, amplifications and deletions have typically been thought to be driven by a single gene, but more than one gene may be implicated in each region (see below). This has important methodological implications, as the hunt for cancer genes may need to be redirected toward genes flanking a common region of amplification or deletion, rather than those at the center.

Renal Cancer, a Paradigm

Renal cell carcinoma (RCC) offers a unique opportunity to study complex relationships among cancer genes. RCC is classified histologically into several types, including clear-cell RCC (ccRCC), the most common type. Positional cloning studies of kindreds with a ccRCC predisposition syndrome, von Hippel–Lindau (VHL), led to the identification of the eponymous gene, VHL (10). Subsequently, VHL was found to be frequently mutated in sporadic ccRCC (11). VHL is mutated in approximately 80% of sporadic ccRCC and is inactivated by methylation in an additional 10% (12, 13). VHL is rarely mutated in other sporadic tumors (14), suggesting that the tumor suppressor function of VHL is limited to a small number of cell types. The VHL gene encodes the substrate recognition subunit of an E3–ubiquitin ligase complex that triggers the degradation of, among others, the α-subunit of hypoxia-inducible factor (HIF) transcription factors (15). The VHL gene is on 3p25.3, and for many years it was thought to explain LOH at 3p in ccRCC.

Interestingly, four tumor suppressor genes have been identified in a relatively small (43 Mb) region on 3p. These genes are: VHL, SET domain containing 2 (SETD2; ref. 16), BRCA1-associated protein-1 (BAP1; refs. 8, 17), and Polybromo 1 (PBRM1; ref. 18). Each functions as a classical two-hit tumor suppressor gene, and an analysis we conducted of previously published data (8, 19) shows that this region is lost in 90% of sporadic ccRCC (Fig. 1). PBRM1 is mutated in approximately 50% of ccRCC (18) and encodes BAF180 (herein referred to as PBRM1), the chromatin targeting subunit of a SWI/SNF nucleosome-remodeling complex. Both SETD2 and BAP1 are mutated in approximately 15% of ccRCC. SETD2 is a histone H3K36 methyltransferase (20) specifically implicated in trimethylation (21). BAP1 is a nuclear deubiquitinase (22, 23), and while substrates have been identified in Drosophila (24) and mammals (25–28), the relevant substrate(s) in RCC remain unknown (8).

Cooperation among tumor suppressor genes on 3p

We performed meta-analyses to test for genetic interactions among 3p genes. Given the mutation frequencies of the different genes, we used PBRM1 as a reference. PBRM1 is mutated at a sufficiently high frequency to be able to draw conclusions and, yet, not uniformly as VHL. We identified studies (or datasets) reporting mutations in PBRM1 together with either SETD2 or BAP1. Adding to the challenge of uncovering genetic interactions (as determined by the frequency of VHL mutations detected), mutation sensitivity was seemingly low across all of the studies available (16, 17, 29).

The Sanger Institute sequenced 348 ccRCC for both PBRM1 and SETD2. One hundred and eleven tumors were found to be solely mutated for PBRM1, and 7 were found solely mutant for SETD2 (18). Given the individual mutation rates for PBRM1 and SETD2, 5 tumors were expected to have mutations in both...
genes, but 8 were found (P = 0.16; Table 1). In a study conducted by Guo and colleagues involving 98 ccRCC, 18 tumors were solely mutant for PBRM1 and 1 was solely mutant for SETD2 (17). Again, given the mutation rates for PBRM1 and SETD2, 1 tumor may have been expected to have mutations in both genes, but 3 were found (P = 0.03; Table 1). Hakimi and colleagues analyzed 185 ccRCC; 48 were found solely mutated for PBRM1 and 8 solely mutated for SETD2. Given these mutation frequencies, 4 double-mutant tumors were expected, but 6 were found (P = 0.24; Table 1). Finally, The Cancer Genome Atlas consortium (TCGA; ref. 30) released results of 293 tumors; 90 tumors were found with mutations in PBRM1 and 17 with mutations in SETD2. Twelve tumors were expected to have mutations in both PBRM1 and SETD2, but 16 were found (P = 0.13; Table 1). Across all the studies, the number of tumors with mutations in both PBRM1 and SETD2 exceeded the number expected by chance alone. However, this difference reached statistical significance only in the study by Guo and colleagues (17). Nonetheless, when considered together, among 924 ccRCC, there were 267 tumors with mutations only in PBRM1, 33 with mutations only in SETD2, and 33 with mutations in both SETD2 and PBRM1 (Table 1). The number of tumors expected to have mutations in both genes by chance alone was 21, and 33 were found. Although the difference in absolute numbers is small, it represents an increase by one third, and the probability that this finding occurred by chance alone is 0.003. Overall, the frequency of mutations in SETD2 was 2-fold higher for PBRM1-mutant tumors than wild-type tumors [odds ratio (OR), 2.1; 95% confidence interval (CI), 1.3–3.5].

NOTE: The data presented here represent the number of tumors with specific mutations and expected frequencies. The range of expected double mutants was calculated on the basis of a hypergeometric distribution. Differences between actual and expected values were evaluated with a Fisher exact test. The Mantel–Haenszel test was used to integrate ORs from the different studies. Data on clear cell renal cell carcinoma (KIRC) were obtained from TCGA (January 2013 release). Data from the combination of these studies (the total) are highlighted in bold. Significant P values are also in bold.
These results suggest that mutations in PBRM1 and SETD2 cooperate in renal tumorigenesis. They assume that mutations occur independently and in the same tumor cells, and functional studies will be required for confirmation. The biologic basis for this cooperation remains to be determined, but plausible models may be proposed on the basis of the function of these proteins, in particular, because both proteins converge on histones, one as writer of a histone mark (SETD2) and the other as a reader (PBRM1). Despite this cooperation, however, no differences in overall survival were found between patients with PBRM1-mutated tumors and those with tumors mutated in both SETD2 and PBRM1 (Supplementary Fig. S1).

Antagonism among tumor suppressor genes on 3p

We reported previously that mutations in PBRM1 and BAP1 are largely mutually exclusive (8), which stands in contrast to the findings from meta-analyses reported herein of PBRM1 and SETD2. Among 176 ccRCC we analyzed, we found 89 tumors with mutations solely in PBRM1 and 21 with mutations solely in BAP1. By chance, 13 tumors would have been expected to have mutations in both genes, but only 3 tumors were found. The probability that this observation was by chance alone was very low (P = 0.00003; ref. 8).

Guo and colleagues and Hakimi and colleagues have also reported BAP1 and PBRM1 mutations in ccRCC (17, 29). In both studies, the sensitivity for mutation detection was seemingly low, and consequently statistical power was insufficient. However, in both instances, fewer tumors were found with simultaneous mutations in both genes than were expected by chance alone (Table 2). Similarly, in data from TCGA, there was an under-representation of tumors with mutations in both BAP1 and PBRM1 (Table 2). In the TCGA study, which is the largest, among 293 tumors, there were 101 with mutations solely in PBRM1 (independently of SETD2) and 22 with mutations solely in BAP1. Given the relative frequencies of tumors individually mutated for BAP1 and PBRM1, 10 tumors would have been expected to have mutations in both genes, but only 5 were found (P = 0.058; Table 2). In the aggregate, these three studies evaluated 576 tumors and among them there were 175 tumors with mutations solely in PBRM1 and 40 with mutations solely in BAP1. Considered together, 14 tumors would have been expected with mutations in both BAP1 and PBRM1, but only 6 were found, and the P value was significant (P = 0.004). Thus, the odds of having a BAP1 mutation in PBRM1-mutant tumors are one third of those for wild-type tumors (OR, 0.29; 95% CI, 0.12–0.70). Although we cannot exclude the possibility that mutation co-occurrence rates may be affected by epigenetic changes (ref. 31; or other factors), these data suggest that simultaneous mutations in BAP1 and PBRM1 are negatively selected for in ccRCC.

Mutation exclusivity is often interpreted to indicate functional redundancy. However, differences in pathologic features, gene expression, and outcomes between tumors with BAP1 and PBRM1 mutations suggest that BAP1 and PBRM1 are not functionally redundant. BAP1-mutant tumors tend to be of high grade, whereas tumors exclusively mutated for PBRM1 are typically of low grade (8). BAP1-mutant tumors, but not PBRM1-mutant tumors, are associated with activation of the mTORC1 pathway (8, 32), a critical pathway in ccRCC (33). BAP1- and PBRM1-mutant tumors are associated with different gene expression signatures. We analyzed 308 ccRCC from the TCGA that had RNA-Seq data available and found that, when compared with the rest, 3,250 genes distinguished the BAP1-mutant group (n = 20) and 2,235 genes distinguished the PBRM1-mutant group (n = 66; ref. 32). In contrast, when groups of tumors were assembled arbitrarily, the number of genes that distinguished these random groups from the rest was less than 200. The differences in the number of genes associated with the BAP1- and PBRM1-mutant groups versus the random groups was highly statistically significant (P < 0.0001; ref. 32). These data indicate that the signatures identified are highly specific. The BAP1- and PBRM1-mutant signatures did not overlap.

NOTE: Number of tumors with specific mutations and expected frequencies. The range of expected double mutants was calculated on the basis of a hypergeometric distribution. Differences between actual and expected values were evaluated with a Fisher exact test. The Mantel–Haenszel test was used to integrate ORs from the different studies. A fixed 0.5 correction was used to find the OR when there was a frequency of 0. Data on clear cell kidney and renal cell carcinoma (KIRC) were obtained from TCGA (January 2013 release). Note that differences in the number of tumors with mutations in PBRM1 shown in Table 1 reflect how tumors are divided according to SETD2 or BAP1 status. Data from the combination of the three studies (the total) are highlighted in bold. Significant P values are also in bold.
Beyond what was expected by chance alone, indicating that they were different (32). BAP1-mutant tumors and PBRM1-mutant tumors are also associated with different outcomes in patients (32). Although the median overall survival for patients with BAP1-mutant tumors is 4.6 years (95% CI, 2.1–7.2), for patients with PBRM1-mutant tumors, the median survival is 10.6 years (95% CI, 9.8–11.5; HR, 2.7 and 95% CI, 0.99–7.6; \( P = 0.044 \); ref. 32).

Taken together, differences in pathology, gene expression, and outcomes strongly suggest that the BAP1 and PBRM1 proteins regulate different processes. Thus, the observation that BAP1 and PBRM1 mutations co-occur in tumors at a frequency lower than expected suggests that, even within a tumor type, a context dependency of tumor suppressor function may exist. Although in some contexts mutations may be tolerated and be advantageous, the same mutations may not be tolerated in other contexts.

The context dependency of tumor suppressor function fits well with the empiric observation that genes exert their tumorigenic properties in a contextual, tissue-dependent manner. This is illustrated in familial cancer syndromes, in which a germline mutation (typically in a tumor suppressor gene) predisposes to a limited spectrum of tumors. Thus, despite the presence of the mutation in all diploid cells, tumors arise in a limited number of tissues. Other factors could help to explain the limited tissue repertoire, including differences in rates of mutation of the remaining allele across cell types. Nonetheless, a limited tumor spectrum is also observed in familial cancer syndromes resulting from germline mutations in oncogenes, such as RET, which are not associated with a mutation of the second allele. Other examples of contextual effects are provided by the overexpression of certain oncogenes, which, depending on the cellular context, may induce senescence or proliferation (34). We conjecture that contextual differences in cancer gene action extend beyond tissue boundaries such that, even within a specific tumor type, there may be permissive and nonpermissive contexts (dictated perhaps by other mutations). Thus, tumors may be viewed as an evolving set of conditional dependencies, which, if understood, may uncover vulnerabilities that could be exploited therapeutically.

A model for ccRCC development

We propose that ccRCC development evolves along two different paths. Following a VHL mutation, which is an early event (35, 36), and the loss of 3p, which is frequently observed (Fig. 1), mutations in the remaining PBRM1 or BAP1 allele may lead to tumors with different characteristics. Thus, tumor aggressiveness may be programmed early during ccRCC development. This model may explain why, despite the discovery of the VHL gene in 1993 (10), a mouse model of ccRCC does not exist today. Interestingly, although the VHL gene is linked to PBRM1 and BAP1 on the same 3p arm in humans, Vhl is on a different chromosome from that of Pbrm1 and Bap1 in the mouse. Thus, loss of homozygosity of the Vhl region in the mouse would not simultaneously inactivate one copy of Pbrm1 and Bap1.

If this model is correct, ccRCC should develop in mice with simultaneous inactivation of Vhl and either Pbrm1 or Bap1 genes, a testable hypothesis currently under evaluation.

Thus, the physical location of cancer genes in the genome may dictate the spectrum of tumors to which a particular species may be predisposed. Thus, in some species, a deletion may eliminate a combination of tumor suppressor genes conducive to tumor development, but if the genes are not collinear in another species, the species may be protected from the corresponding tumor type.

The physical location of tumor suppressor genes may also have implications within a species. For example, the type of second hit mutation observed may depend on whether there are neighboring tumor suppressor genes that function as such in the specific tissue. For instance, BAP1 is mutated in mesothelioma (37, 38), ccRCC (8, 17), and uveal melanoma (39–41). However, the “second-hit” mutation may be different in the three tissues. In mesothelioma, focal mutations may inactivate the second allele (38), whereas in ccRCC the second allele is typically inactivated by loss of 3p (Fig. 1), and in metastatic uveal melanoma through whole chromosome 3 loss (39). These data are consistent with the notion that VHL (as well as SETD2 and PBRM1) may not function as a tumor suppressor gene in mesothelioma, in contrast with ccRCC. The data also suggest the existence of other tumor suppressor genes in metastatic uveal melanoma in 3q. We speculate that differences in the type of second-hit mutation across tissues illustrate tissue-specific differences in tumor suppressor gene activities and tumor suppressor gene cooperation.

The type of second-hit mutation may also depend on noncancer genes. Noncancer genes may be subject to dosage effects, and these effects may be context or tissue specific. Thus, a large deletion may be poorly tolerated in some tumor types as it may uncover tissue-specific haploinsufficient genes, diminishing, thereby, the fitness of the tumor cell.

Conclusions

Improved functional annotation of mutations in cancer genes and an understanding of mutant allele ratios and mutation prevalence in tumors should facilitate the development of genetic interaction maps. To uncover the full spectrum of genetic interactions among cancer genes, adequate statistical power is necessary and meta-analyses may be required. Large deletions in tumors may be driven by the loss of more than one tumor suppressor gene, and syntetic differences may explain differential tumor predisposition across species. Together with the notion that tumor suppressor genes function as such in a tissue-restricted manner, the physical location of a gene may explain the type of second-hit mutation and the architecture of deletions across different tumor types. Understanding genetic interactions among driver genes and context dependencies of oncogenic (or tumor suppressor) action, which extend beyond tissue boundaries, may expose vulnerabilities that could be exploited therapeutically.
