FOXL1, a Novel Candidate Tumor Suppressor, Inhibits Tumor Aggressiveness and Predicts Outcome in Human Pancreatic Cancer

Geng Zhang1, Peijun He1, Jochen Gaedcke3, B. Michael Ghadimi3, Thomas Ried2, Harris G. Yfantis4, Dong H. Lee4, Nader Hanna5, H. Richard Alexander5, and S. Perwez Hussain1

Abstract

The forkhead box L1 (FOXL1) transcription factor regulates epithelial proliferation and development of gastrointestinal tract and has been implicated in gastrointestinal tumorigenesis in mouse models. However, the role of FOXL1 in pancreatic cancer development and progression remains to be elucidated. Here, we report that higher expression of FOXL1 is significantly associated with better clinical outcome in human pancreatic ductal adenocarcinoma (PDAC). A lower FOXL1 expression is correlated with metastasis and advanced pathologic stage of pancreatic cancer. Mechanistic analyses showed that overexpression of FOXL1 induces apoptosis and inhibits proliferation and invasion in pancreatic cancer cells, whereas silencing of FOXL1 by siRNA inhibits apoptosis and enhances tumor cell growth and invasion. Furthermore, FOXL1 overexpression significantly suppressed the growth of tumor xenografts in nude mice. FOXL1 promoted apoptosis partly through the induction of TNF-related apoptosis-inducing ligand (TRAIL) in pancreatic cancer cells. In addition, FOXL1 suppressed the transcription of zinc finger E-box–binding homeobox 1 (ZEB1), an activator of epithelial–mesenchymal transition, and the negative regulation of ZEB1 contributed to the inhibitory effect of FOXL1 on tumor cell invasion. Taken together, our findings suggest that FOXL1 expression is a candidate predictor of clinical outcome in patients with resected PDAC and it plays an inhibitory role in pancreatic tumor progression. Cancer Res; 73(17); 5416–25. ©2013 AACR.

Introduction

Pancreatic cancer is the fourth leading cause of cancer-related death in the United States (1). The median survival of all pancreatic ductal adenocarcinoma (PDAC) cases is less than 6 months, and only 6% of patients survive 5 years after diagnosis. The dismal prognosis in pancreatic cancer is due to late diagnosis and the lack of effective treatment. A better understanding of the molecular mechanism of this disease and discovery of novel therapeutic targets are desperately needed to improve outcomes in patients with PDAC.

Forkhead box L1 (FOXL1) proteins belong to the forkhead family of transcription factors. Fox family shares a highly conserved 100-amino acid DNA-binding domain (the forkhead box) and comprises more than 100 members in humans, classified as FOXA to FOXR on the basis of sequence similarity (2). Fox proteins are at the junction of multiple signaling pathways and play critical roles in a variety of physiologic and pathologic processes including cancer. For example, FOXOs can initiate apoptosis and promote cell-cycle arrest (3). In addition, FOXL1 deficiency in genetic mice led to the development of thymic lymphomas and hemangiomas, indicating that the FOXOs are tumor suppressors (4, 5). In contrast to FOXOs, FOXM1 has been shown to have proproliferative function, and increased expression of FOXM1 gene was often found in various human cancers (6). In pancreatic cancer, overexpression of FOXM1 is associated with poor prognosis and pathologic stage of PDAC (7). Downregulation of FOXM1 results in the inhibition of migration, invasion, and angiogenesis of PDAC (8). FOXL1 has been implicated in the regulation of epithelial cell proliferation in gastrointestinal tracts. Loss of Foxl1 led to a marked increase in cellular proliferation of intestinal epithelia in mice, leading to the distortion in the tissue architecture of the stomach and small intestine (9). The altered proliferation rate in Foxl1-null–mutant mice is correlated with an activated Wnt/β-catenin pathway as showed by increased nuclear translocation of β-catenin (10). Foxl1 deficiency accelerates the initiation of gastrointestinal tumor and increases tumor load in Apcmin mice (11). FOXL1 is specifically expressed in low-grade fibromyxoid sarcoma (LGFM5), as compared with other
morphologically similar tumor types including myxofibrosarcoma, desmoid fibromatosis, extraskeletal myxoid chondrosarcoma, and solitary fibrous tumors, suggesting its role in LGFMS (12). Thus far, the biologic function of FOXL1 in human cancer remains to be elucidated. In the present study, we investigated the role of FOXL1 in human pancreatic cancer. Our data showed that FOXL1 expression is associated with clinical outcomes, pathologic stages, and metastasis of pancreatic cancer. Furthermore, mechanistic studies showed that FOXL1 inhibits cellular proliferation and invasion in pancreatic cancer cells. Moreover, we investigated the potential transcriptional targets of FOXL1, which may contribute to the inhibitory effects of FOXL1 on the growth and invasion in human pancreatic cancer cells.

Materials and Methods

Tissue collection and RNA isolation

Pairs of primary pancreatic tumor and adjacent non-tumor tissues came from 45 patients with PDAC at the Department of General and Visceral Surgery, University Medicine Göttingen (Göttingen, Germany). Tissues were flash frozen immediately after surgery. Demographic and clinical information for each case included age, sex, grade, clinical staging, resection margin status, and survival times from diagnosis (Supplementary Table S1). Tumor histopathology was classified according to the World Health Organization Classification of Tumor system (13). Use of these clinical specimens was reviewed and permitted by the National Cancer Institute (NCI)-Office of the Human Subject Research (OHSR, Exempt # 4678) at the NIH (Bethesda, MD). RNA from frozen tissue samples was extracted using standard TRIzol (Invitrogen,) protocol. RNA quality was confirmed with the Agilent 2100 Bioanalyzer (Agilent Technologies).

Quantitative reverse transcriptase PCR

Total RNA was reverse transcribed using High-Capacity cDNA Reverse Transcription Kit (Applied Biosystems). Quantitative reverse transcriptase PCR (qRT-PCR) reactions in 384-well plates were carried out using TaqMan gene expression assays on an ABI Prism 7900HT Sequence Detection instrument (Applied Biosystems). Expression levels of ACTB and glyceraldehyde-3-phosphate dehydrogenase were used as the endogenous controls. All assays were conducted at least in triplicates. For quality control, any samples with a gene cycle value more than 36 were considered of poor quality and removed. If a tumor or non-tumor sample failed quality control from qRT-PCR that case was removed from the analysis. All the primers for qRT-PCR in the present study were purchased from Applied Biosystems.

Immunohistochemistry

Five-micrometer thick paraffin sections of tumors and surrounding non-tumor tissues from resected PDAC cases were incubated with mouse monoclonal anti-FOXL1 antibody (Abnova). Signals were amplified using biotinylated immunoglobulin G (IgG), followed by horseradish peroxidase-conjugated avidin–biotin complex (Vectastain ABC Kit, Vector Lab). Diaminobenzene was used as the chromogen (Dako Envision System). Immunostaining was evaluated blindly by two Board-certified pathologists assigning the intensity and prevalence score as described elsewhere (14). Briefly, the intensity was assigned a score of 0–3, representing negative, weak, moderate, or strong expression, whereas, prevalence was assigned a score of 0–4 representing less than 10%, 10%–30%, 30%–50%, 50%–80%, and more than 80% cells showing FOXL1 expression. The overall quantitation of IHC score was then achieved by multiplying the intensity and prevalence score as described elsewhere (15). IHC images were photographed under an Olympus BX40 microscope.

Cell lines and culture conditions

Human pancreatic carcinoma cell lines Panc1 (CRL-1469), MiaPaCa2 (CRL-1420), and Capan-1 (HTB-79), were obtained from American Type Culture Collection. Cells were maintained in Gibco RPMI Media 1640 supplemented with GlutaMAX-I (Invitrogen), penicillin–streptomycin (50 IU/mL and 50 mg/mL, respectively), and 10% (v/v) fetal calf serum. Cells were incubated at 37°C in a humidified atmosphere with 10% CO2. Transfection of the plasmid was conducted using Lipofectamine LTX reagent according to the manufacturer’s protocol (Invitrogen). Plasmid pCMV-CTRL was used for transfection as the negative control. Plasmid pCMV-FOXL1 was used for FOXL1 overexpression. ON-TARGETplus siRNAs targeting to FOXL1 or zinc finger E-box–binding homeobox 1 (ZEB1) and DrhamaFECT–4 (Dharmacon) were used for silencing FOXL1 or ZEB1 expression in pancreatic cancer cells.

MTT assay

Cells were seeded in 96-well plates (3,000 cells/well) and incubated for 2 to 10 days. Then, the MTT solution was added and incubated for 4 hours. After the MTT solution was aspirated, 100 μL dimethylsulfoxide was added to each well. The absorbance was measured at 570 and 650 nm.

Apoptosis assay

Pancreatic cancer cell lines were seeded and transfected with FOXL1 overexpression vectors or siRNAs directly targeting FOXL1 mRNA. Caspase activity was measured by Apo-ONE Homogeneous Caspase-3/7 Assay (Promega) and potency of caspase activation was calculated and compared with control cells.

Quantification of TRAIL protein level by ELISA

Cells were transfected with either control vector pCMV-CTRL or pCMV-FOXL1 expression vectors, respectively. Twenty-four hours after transfection, cells were sorted and aliquoted in sample tubes (5 × 10^6 cells/sample). Cells were lysed (5 × 10^5 cells/100 μL lysis buffer) and TNF-related apoptosis-inducing ligand (TRAIL) production in cell lysates was measured using Quantikine Human TRAIL/TNFSF10 ELISA Kit (R&D Systems) according to the manufacturer’s instructions. Optical density of each well was then determined using a microplate reader set to 450 nm. TRAIL concentrations were calculated using a standard curve and linear regression analysis.
Subcutaneous xenografts in nude mice

All animal experiments and maintenance conformed to the guidelines of the Animal Care and Use Committee and of the American Association of Laboratory Animal Care. A total of 5 × 10⁶ FOXL1-overexpressing cells and control Panc1 cells in a total volume of 100 μL of 1/1 (v/v) PBS/Matrigel (BD Biosciences) were injected subcutaneously into flanks of 8–9-week old male athymic nu/nu mice (Harlan Laboratories) with 5 mice per arm. One week after the injection of tumor cells, subcutaneous tumor volumes (V) were measured weekly with digital calipers (Fisher Scientific) and calculated using the formula V = 1/2(a²b), where a is the biggest and b is the smallest orthogonal tumor diameter. After 6 weeks, all mice were sacrificed and xenografts were resected and measured. Differences in tumor growth were compared by the two-way repeated measures ANOVA and comparisons of tumor weight between the groups were made using the two-tailed Student t test. P < 0.05 is considered significant.

Cell invasion assay

Pancreatic cancer cell invasion assay was conducted in 24-well Biocoat Matrigel invasion chambers (8 μm; Becton Dickinson) according to the manufacturer’s protocol. Briefly, cells were transfected with either control vector pCMV-GFP or pCMV-FOXL1-GFP expression vectors, respectively. Twenty-four hours after transfection, the cells were harvested and plated in the top chamber (5 × 10⁵/well). The bottom chamber contained 10% FBS as a chemoattractant. Forty-eight hours after incubation, the noninvasive cells were removed with a cotton swab. The invasive cells migrate through the membrane and stick to the lower surface of the membrane. GFP-positive cells were counted under a fluorescence microscope in five fields (× 20 magnification). Data are expressed as the percentage of invasion according to the manufacturer’s manual: the number of the cells invading through the Matrigel membrane divided by the number of cells migrating through the control membrane. All assays were conducted in triplicate and repeated three times.

Luciferase assay

Human ZEB1 or TRAIL promoter fragment was amplified from genomic DNA by PCR and cloned into pGL4Basic vector (Promega). Briefly, 1 μg pCMV-FOXL1 (or pCMV-CTRL) and 1 μg of firefly-luciferase reporter plasmid (pGL4-ZEB or pGL4-TRAIL) together with 10 ng of a Renilla luciferase transfection control (pRL-TK; Promega) were incubated overnight with subconfluent cell cultures in each well of a 24-well plate. The cells were then washed twice in PBS and harvested for firefly/Renilla luciferase assays using the Dual-Luciferase Reporter Assay System (Promega).

Chromatin immunoprecipitation assays

Chromatin immunoprecipitation (ChIP) assays were conducted according to the manufacturer’s instructions (Qiagen). Briefly, Panc1 cells were transfected with pCMV-FOX1-GFP. Forty-eight hours after transfection, formaldehyde was added to cell culture media to a final concentration of 1% and then the cells were incubated for 10 minutes on a shaking platform at room temperature. After the addition of glycine at concentrations of up to 0.136 mol/L, cells were incubated for 5 minutes and then washed with cold PBS. Cell pellets were obtained, resuspended in SDS lysis buffer, and sonicated with a Bioruptor (Cosmo Bio,) for 30 seconds at maximum setting 10 times at 1-minute intervals. Immunoprecipitation was carried out overnight at 4°C with rotation, using antibodies specific for GFP (Origene) or mouse control IgG. After incubation with protein A, the beads were collected, washed, and eluted per manufacturer’s instructions. Cross-links were reversed by incubation for 6 hours at 65°C and DNA was purified from the supernatant by phenol/chloroform extraction and ethanol precipitation. Precipitated DNA was analyzed by qRT-PCR. The PCR primer pairs spanned upstream of promoter region of the human ZEB1 gene (GenBank accession number NM_001128128): (1) forward, 5'-TTGAGGGGCTGAGGAGGCT-3'; reverse, 5'-CAGCGGCACAGGGGCA-3'; (2) forward, 5'-GCAAGGAGGTACAGGCCCA-3'; reverse, 5'-TTGAGCCCCCACCACAACA-3'; (3) forward, 5'-TGGAGCCTCCCTACGGTTT-3'; reverse, 5'-ACGCCCCGAACCTTGTGCT-3'; (4) forward, 5'-TTTGTGCTGCTGTGCCAAGGGCA-3'; reverse, 5'-AAAGCGAGCTGGGCAACACCA-3'. The PCR primer pairs spanned upstream of promoter region of the human TRAIL gene (TRAIL, GenBank accession number NM_003810.2): (1) forward, 5'-TTGACCGGAACCTTGTTGCT-3'; reverse, 5'-TGACGATCGACGGTCCCTAACGGTTT-3'; (2) forward, 5'-ACGGCCGGAACCTTGTTGCT-3'; reverse, 5'-TTTGCGCTGCTGCTGCCAAGGGCA-3'; reverse, 5'-AAAGCGAGCTGGGCAACACCA-3'. The PCR primer pairs spanned upstream of promoter region of the human ZEB1 gene (GenBank accession number NM_001128128): (1) forward, 5'-TTGACCGGAACCTTGTTGCT-3'; reverse, 5'-TGACGATCGACGGTCCCTAACGGTTT-3'; (2) forward, 5'-ACGGCCGGAACCTTGTTGCT-3'; reverse, 5'-TTTGCGCTGCTGCTGCCAAGGGCA-3'; reverse, 5'-AAAGCGAGCTGGGCAACACCA-3'.

Statistical analysis

Expression graphs and Student t test were used to analyze differences in gene expression using GraphPad Prism 5.0 (GraphPad Software Inc). Kaplan–Meier analysis was conducted with GraphPad Prism 5.0. Cox proportional hazards regression analysis was conducted using Stata 11 (StataCorp LP). Univariate Cox regression was conducted on genes and clinical covariates to examine influence of each on patient survival. Final multivariate models were based on stepwise addition and removal of clinical covariates found to be associated with survival in univariate models (P < 0.05). For these models, resection margin status was dichotomized as positive (R1) versus negative (R0); tumor-node-metastasis staging was dichotomized as I–II versus III–IV. All stepwise addition models gave the same final models as stepwise removal models. All univariate and multivariate Cox regression models were tested for proportional hazards assumptions based on Schoenfeld residuals, and no model violated these assumptions. The statistical significance was defined as P < 0.05. All P values reported were two-sided.

Results

Higher FOXL1 is associated with better clinical outcome in pancreatic cancer

We conducted qRT-PCR for FOX1 in 45 tumor samples of PDAC and analyzed its association with disease outcome. We dichotomized high and low expression of FOX1 as values...
Univariate Cox regression analysis in PDAC cases showed that a higher FOXL1 expression (HR, 0.44; 95% confidence interval (CI), 0.20–0.95; P = 0.036) and differentiation grade (HR, 2.77; 95% CI, 1.12–6.87; P = 0.027) were each associated with prognosis but not the tumor stage or resection margin status (Table 1). Multivariate analyses revealed that higher FOXL1 expression was an independent predictor of better survival (HR, 0.41; 95% CI, 0.19–0.89; P = 0.024). In addition, the multivariate model including FOXL1 and grade was significantly better at predicting prognosis in PDAC than grade alone (P < 0.05, likelihood ratio test), indicating the prognostic significance of FOXL1 in resected PDAC.

Immunohistochemical (IHC) analysis of tumors and adjacent nontumor tissues from PDAC cases showed predominant nuclear localization of FOXL1 in pancreatic ductal cells and acinar cells (Fig. 1B). PDAC cases with higher FOXL1 mRNA level determined by qRT-PCR also showed higher IHC staining score (Student t test, P < 0.05). FOXL1 expression was significantly higher in earlier stage (I + II) as compared with the late stage tumors (III + IV; Student t test, P < 0.01; Fig. 1C). Fisher exact test showed that a lower expression of FOXL1 is significantly correlated with PDAC cases with lymph node and distant metastases (P < 0.01; Fig. 1D). These data indicated that FOXL1 may be involved in tumor progression and aggressiveness of pancreatic cancer.

**FOXL1 suppresses tumor growth of pancreatic cancer**

The association of lower FOXL1 expression with increased cancer-specific mortality suggests its potential inhibitory role in pancreatic tumor progression. To test this hypothesis, we first assessed the effect of FOXL1 on the proliferation and growth of pancreatic cancer cells. Panc1 and MIApaca2 pancreatic cancer cells with a lower level of endogenous FOXL1 expression (Supplementary Fig. S1) were transfected with pCMV-FOXL1 expression construct. An elevated expression of FOXL1 was showed using qRT-PCR and Western blot analyses in cells transfected with pCMV-FOXL1, as compared with control cells (Fig. 2A). Overexpression of FOXL1 significantly inhibited cell proliferation in both Panc1 and MIApaca2 cells (P < 0.05; Fig. 2B). The colony formation assay confirmed the inhibitory effect of FOXL1 on cell growth, showing a significant decrease in colony number of FOXL1-overexpressing cells compared with control cells (P < 0.01, Fig. 2C). In contrast, knockdown of FOXL1 in pancreatic cancer cells using siRNA significantly increased cell growth (P < 0.05, Supplementary Fig. S3C).

To further investigate the role of FOXL1 in tumor growth of pancreatic cancer in *vivo*, we extended our investigation by subcutaneous implantation of FOXL1 overexpressing and control Panc1 cells in nude mice. Tumor growth was significantly suppressed in cells overexpressing FOXL1 as compared with control cells (P < 0.05, Fig. 2D). Overexpression of FOXL1 led to a significant reduction in tumor volume (P < 0.05) and tumor weight (P < 0.01; Fig. 2D). These *in vivo* findings showed that FOXL1 suppresses the tumor growth of pancreatic cancer cells.
FOXL1 increases TRAIL expression and promotes apoptosis  
To determine the role of FOXL1 in regulating apoptosis in pancreatic cancer cells, we examined the caspase-3 activity in FOXL1-overexpressing Panc1 and MIAPaca2 cells. Overexpression of FOXL1 led to a significant increase in caspase-3/7 activity in Panc1 and MIAPaca2 cells (P < 0.01, Fig. 3A), whereas silencing of FOXL1 by siRNA reduced apoptosis as determined by caspase-3/7 activity (P < 0.01, Supplementary Fig. S3D). To elucidate the underlying mechanism of the regulation of apoptosis by FOXL1, we then analyzed expressions of a panel of apoptosis-related genes in response to the overexpression of FOXL1 using qRT-PCR and found that FOXL1 overexpression induced proapoptotic gene TRAIL expression by about 2.5-fold in pancreatic cancer cell lines as compared with controls (P < 0.01, Fig. 4B). In contrast, knockdown of FOXL1 promoted pancreatic cancer cell invasion (P < 0.05, Supplementary Fig. S3B).

FOXL1 binds to the promoter of ZEB1 and suppresses ZEB1 transcription  
ZEB1 functions as an epithelial–mesenchymal transition (EMT) activator, promoting cancer cell invasion and aggressiveness (17). It has been reported that ZEB1 expression is higher in Panc1 and MIAPaca2, pancreatic cancer cell lines with mesenchymal features, as compared with HPAF, Capan1, and Capan2 cell lines with epithelial features (18). We observed an inverse association between FOXL1 and ZEB1 expressions in pancreatic cancer cell lines (Supplementary Fig. S1). Quantitative RT-PCR and Western blot analyses showed that FOXL1 was higher in HPAF, Capan1, and Capan2 cell lines and lower in Panc1 and MIAPaca2 cells (Supplementary Fig. S1). We then tested the hypothesis that a higher level of FOXL1 suppresses ZEB1 expression. Quantitative RT-PCR and Western blot analyses showed that overexpression of FOXL1 significantly inhibited ZEB1 expression in Panc1 and MIAPaca2 cells (Fig. 5A). In contrast, knockdown of FOXL1 increases the expression of ZEB1 (P < 0.05, Supplementary Fig. S1). To determine whether ZEB1 is involved in inhibitory effect of FOXL1 on cell invasion in pancreatic cancer, pancreatic cancer cell lines were transfected with si-FOXL1 alone or together with si-ZEB1. The stimulatory effect of FOXL1 knockdown on cell invasion was ablated by simultaneous siRNA-mediated knockdown of ZEB1 (Supplementary Fig. S3B). These data indicated that the negative regulation of ZEB1 may contribute to the inhibitory effect of FOXL1 on invasion ability of pancreatic cancer cells.

Analysis of ZEB1 promoter to identify potential forkhead box–binding sites using TRANSFAC program revealed 4 regions containing multiple potential FOXL1-binding sites at the upstream of transcription start site of ZEB1 (Fig. 5B). To further investigate the mechanism of FOXL1-mediated regulation of ZEB1, ChIP-PCR assays were conducted to determine whether a physical interaction exists between FOXL1 protein and the promoter region of ZEB1. We pulled down FOXL1-targeted DNA fragments and probed for 4 fragments representing different ZEB1 promoter regions by qRT-PCR (Fig. 5C).
The strongest association was detected around region-4 within the ZEB1 promoter ($P < 0.01$). We next tested whether this interaction affects ZEB1 transcription. The promoter region of ZEB1 harboring region-4 was inserted into the pGL4 basic reporter vector (pGL4-ZEB1). Luciferase activity was determined following cotransfection of pGL4-ZEB1 with pCMV-FOXL1 or pCMV control vector. As shown in Fig. 5D, the luciferase activities of pGL4-ZEB1 were significantly decreased when it was cotransfected with pCMV-FOXL1 compared with pCMV-CTRL ($P < 0.01$, Fig. 5D). These findings showed that FOXL1 bound to the promoter region of ZEB1 and suppressed transcription and promoter activity of ZEB1.

Figure 2. FOXL1 inhibits pancreatic tumor growth. A, increased expression of FOXL1 in transfected pancreatic cancer cells were showed by qRT-PCR and Western blot analysis. B, there were significant decreases in cell growth of FOXL1-overexpressing cells as compared with control cells. C, FOXL1-overexpressing cells exhibited reduced colony formation as compared with control cells. Data are presented as means ± SD from 3 independent experiments. *, $t$ test $P < 0.05$; **, $t$ test $P < 0.01$. D, subcutaneous implantation of FOXL1-overexpressing Panc1 cells in nude mice showed a significant decrease in tumor growth as compared with control cells.
Discussion

FOXL1 was previously described as a critical transcriptional factor that regulates cell proliferation and development of epithelium in gastrointestinal tracts in mice (9). We conducted Oncomine database analyses on publicly available microarray datasets and found that FOXL1 expression is consistently decreased in multiple myeloma as compared with normal tissues, with a cut-off \( P < 0.05 \) in microarray studies (19–21). One myeloma dataset also showed that FOXL1 is significantly higher in long survival (alive over a year) as compared with short survival group (dead within a year; ref. 20). However, differential expression of FOXL1 between pancreatic tumors and nontumors in available microarray datasets from Oncomine are inconsistent (Supplementary Fig. S2). A lower FOXL1 expression was found in pancreatic tumors as compared with nontumor pancreas tissues in two publicly available microarray datasets (22, 23). Interestingly, Ishikawa and colleagues' data showed that FOXL1 level was significantly lower in pancreatic juice from patients with pancreatic cancer than in healthy donors (24). In contrast, overexpression of FOXL1 in tumors was found in Pei and colleagues' dataset (25) and no significant difference exists in FOXL1 expression between tumor and normal tissues in Grutzmann and colleagues' dataset (26). Gene expression profile of Prasad and colleagues' dataset showed a higher gene expression of FOXL1 in microdissected early PanIN lesions as compared with microdissected normal duct epithelium (27). In our study, IHC analysis, which allows us to compare the FOXL1 expression in ductal cells, showed that low FOXL1 expression is correlated with metastasis and advanced pathologic stage of pancreatic cancer (Fig. 1). Moreover, our data showed for the first time that a higher FOXL1 expression is associated with better clinical outcome in resected PDAC cases. Functional studies revealed that restoration of FOXL1 in Panc1 and MIApaca2 pancreatic cancer cells significantly promoted apoptosis, inhibited cell proliferation, suppressed cell invasion, and inhibited Panc1 tumor growth in nude mice. Taken together, our findings support the inhibitory role of FOXL1 in pancreatic cancer.

Furthermore, we identified ZEB1 as a novel transcriptional target of FOXL1. ZEB1, encoded by the TCF8 gene, plays an important role in invasion and metastasis of human tumors (17). Enforced expression of ZEB in epithelial cells results in a rapid EMT associated with a breakdown of cell polarity, loss of cell–cell adhesion, and induction of cell motility (28). Expression of ZEB1 promotes metastasis of tumor cells in a mouse xenograft model (29). Vice versa, knockdown of ZEB factors in cancer cells inhibit cell invasion (30). In this study, we showed that FOXL1 protein directly binds to ZEB1 promoter and
suppresses the transcription and promoter activity of ZEB1 (Fig. 5). Our data indicate that inhibition of ZEB1 expression by FOXL1 may contribute to the inhibitory effect of FOXL1 on invasive ability of pancreatic cancer cells.

Apoptosis plays a critical role in tumorigenesis. Several members of Fox family have been linked to the regulation of apoptosis in cancer (31). For example, FOXO proteins regulate cell survival by modulating the expression of death receptor ligands (such as FasL and TRAIL), which function in autocrine and paracrine manners (16, 32). In addition to the death receptor ligands, FOXO proteins have been shown to be involved in the transactivation of the Bcl-2 family, which has both pro- and antiapoptotic members and plays a critical role in regulating cell survival (33, 34). In our study, the induction of apoptosis by FOXL1 seemed to be associated with upregulation of TRAIL expression.

TRAIL an attractive candidate for cancer therapy (41). TRAIL has been reported to induce apoptosis in a wide spectrum of cancer cell lines including pancreatic cancer cell lines, with no or minimal toxicity on normal human cells (42–45). We found that enforced expression of FOXL1 resulted in an increased TRAIL expression in pancreatic cancer cells, which eventually led to the elevated caspase-3 activity in these cells (Fig. 3). There was no difference in TRAIL-R1 or R2 expression in FOXL1-overexpressing cells as compared with control cells. We also found approximately 1.5-fold increase in Fas expression in FOXL1-overexpressing cells as compared with control cells. We also found approximately 1.5-fold increase in Fas expression in these cells (Supplementary Fig. S4). However, several studies have shown that PDAC is resistant to Fas/CD95-mediated apoptosis, even though both Fas receptor and Fas ligand are frequently expressed in PDAC cells (46, 47). Thus, increased Fas expressions have limited impact on the induction of apoptosis by FOXL1, at least in pancreatic cancer.

In summary, our findings showed for the first time that FOXL1 plays an inhibitory role in pancreatic cancer. Overexpression of FOXL1 promoted apoptosis, suppressed cellular growth and invasion in pancreatic cancer cells, at least partly through regulation of TRAIL and ZEB1 expression, and inhibited tumor growth in nude mice. These results are consistent with our finding that a higher FOXL1 expression is associated with a lower risk of cancer development.

Figure 4. FOXL1 inhibits cell migration and invasion of pancreatic cancer cells. A, cell migration was assessed using scratch-healing assays. Confluent monolayer of Panc1 and MIApaca2 cells were scratched and healing was monitored by taking photographs at the indicated time points. B, cell invasion was determined in Panc1 and MIApaca2 cells using Biocoat Matrigel invasion assay. The invaded cells were counted under a microscope. Data represent means ± SD from 3 independent experiments. **, *t* test *P* < 0.01.
with better clinical outcome in patients with PDAC. Therefore, we propose that FOXL1 may function as a potential tumor suppressor and serve as a candidate predictor of outcomes in pancreatic cancer. Further studies are warranted to determine the molecular mechanism driving the loss of FOXL1 during pancreatic cancer progression and how the restoration of FOXL1 can be harnessed for therapeutic benefit.
