Priority Report

A Model of Postsurgical Advanced Metastatic Breast Cancer More Accurately Replicates the Clinical Efficacy of Antiangiogenic Drugs

Eric Guerin, Shan Man, Ping Xu, and Robert S. Kerbel

Abstract

The failure rate of randomized phase III oncology clinical trials is extremely high, even when preceded by encouraging preclinical studies and phase II trial results of the same therapy. Thus, there is considerable effort being made to improve the predictive clinical potential of preclinical models, in addition to improving phase II trial design. With respect to the former, preclinical models have historically relied heavily on treatment of primary spontaneous or transplanted tumors rather than the more common and therapeutically challenging clinical trial circumstance of advanced metastatic disease. Here, we show that the oral antiangiogenic tyrosine kinase inhibitor (TKI), sunitinib, which failed to meet primary or secondary survival endpoints in 4 separate phase III metastatic breast cancer (MBC) trials, either alone or with chemotherapy, similarly failed to show monotherapy or combination chemotherapy efficacy in a model of postsurgical advanced MBC using a metastatic variant of the MDA-MB-231 triple-negative human breast cancer. In contrast, the drug was effective when used to treat established orthotopic primary tumors. Similar results were obtained with pazopanib monotherapy, another antiangiogenic oral TKI. However, when an antibody targeting the VEGF pathway (DC101) was tested, it showed a trend in modestly improving the efficacy of paclitaxel therapy, thus resembling to a degree prior phase III clinical results of bevacizumab plus paclitaxel in MBC. Our results suggest the potential value of treating postsurgical advanced metastatic disease as a possible strategy to improve preclinical models for predicting outcomes in patients with metastatic disease. Cancer Res; 73(9); 2743–8. ©2013 AACR.

Introduction

An enduring problem in oncology experimental therapeutics has been the limited value of models involving treatment of tumor-bearing mice to consistently predict outcomes later assessed in clinical trials, particularly at the randomized phase III level (1–4). A common scenario observed is positive and sometimes even remarkable preclinical activity, which is then followed by complete failure in the clinic (1–4). Such failures add substantially to the cost of approved agents as well as exposing patients with cancer enrolled in such trials to ineffective therapies. As a result, there is considerable effort to identify potential causes for this discrepancy and develop significantly improved preclinical models (1–4) such as genetically engineered mouse models (GEMM) of cancer and patient-derived xenografts (PDX) as opposed to the historically more common use of transplantation of established cultured tumor cell lines grown as solid primary tumors.

Although many factors have been proposed for the discrepant therapeutic outcomes observed between preclinical and clinical studies (1–4), one factor, which has received scant attention, is the failure to duplicate in mice treatment of advanced visceral metastatic disease (5, 6). Most phase I and II solid tumor clinical trials and the majority of phase III trials involve patients with such disease. In many or most cases the primary tumor has been surgically resected. The failure rate is extremely high in phase III metastatic therapy trials (7) and when therapies succeed, the benefits in survival are frequently incremental (8). Therefore we have developed several models of postsurgical advanced metastatic disease using established human tumor cell lines grown in immunodeficient mice to mimic the more challenging circumstance of treating patients with metastatic disease (5). In most cases, the cell lines used are variants previously selected in vivo for aggressive spontaneous metastatic spread after the primary orthotopic tumor has been surgically resected (5). One such variant, called LM2-4, was serially selected in vivo from the commonly used MDA-MB-231 triple-negative human breast cancer cell line (9).

Here, we report the use of the aforementioned postsurgical model of LM2-4 to evaluate the impact of several antiangiogenic drugs, used alone or in combination with paclitaxel chemotherapy, and compare the results obtained with conventional treatment of established primary tumors. One of the
drugs we tested is sunitinib (Sutent), an oral tyrosine kinase inhibitor (TKI), which targets VEGF receptors (VEGFR) and platelet-derived growth factor receptors, among several others (10). Based partly on very encouraging preclinical results in 3 different established primary breast cancer models (a transgenic model, a chemically-induced rat model, and a human tumor xenograft model; ref. 10) and a bone colonization experiment (10), sunitinib was subsequently evaluated in patients with metastatic breast cancer (MBC); 4 independent phase III trials were undertaken (11–15), 3 in combination with chemotherapy (paclitaxel, or docetaxel, or capecitabine). All 4 trials failed to meet efficacy endpoints of survival (11–15). This stands in contrast to a phase III trial involving the anti-VEGF antibody, bevazicuzumab (Avastin), when used with chemotherapy, for example, paclitaxel, which provided a clinical benefit, at least in progression-free survival (PFS), though not in overall survival (OS; ref. 16). We also tested another antiangiogenic TKI, pazopanib and a monoclonal antibody that targets the mouse VEGFR-2 (DC101). Sunitinib and DC101 were also evaluated with concurrent paclitaxel chemotherapy.

The purpose of these studies was to further validate the preclinical strategy of using postsurgical models of advanced metastatic disease to predict clinical outcomes involving treatment of patients with metastatic disease by addressing the following questions and comparing the results with prior phase III trial outcomes: (i) is it the case that antiangiogenic drug monotherapy has reduced or no therapeutic benefit when treating mice with advanced metastatic disease in contrast to established primary tumors? (ii) What is the impact on outcomes when chemotherapy is used in combination with the antiangiogenic agent? And. (iii) is there a difference in outcomes when using TKIs versus antibodies in combination with chemotherapy?

Materials and Methods

Female CB-17 severe combined immunodeficient (SCID) mice were purchased from Charles River, and female YFP SCID mice (17) were bred in house from breeding pairs generously provided by Dr. Janusz Rak (McGill University, Montreal). Mice at 6 to 8 weeks of age were used. MDA-MB 231/LM2.4 is a variant cell line of MDA-MB 231 selected in vivo for aggressive spontaneous metastatic spread from established but resected primary tumors and was grown in cell culture as previously described (9). Cell line authentication was carried out by genotyping using Illumina mouse linkage panel and confirmed to be human in origin. Routine mycoplasma screening is carried out in-house using commercial kits, which confirmed the cell line is mycoplasma free. Mammary fat pad injection (2 × 10^6 cells) was carried out as previously described (9). Weekly caliper measurements were carried out to determine tumor growth and tumor volume was calculated using the formula \( a^2 b/2 \), where \( a \) is the width and \( b \) is the length. Treatment of primary tumors was initiated when average volume was approximately 100 to 150 mm³, that is, 12 to 15 days after cell injection. Surgical resection of the primary tumors was carried out when the average tumor size was 400 mm³.

All mice were randomized just before initiation of treatment. Antiangiogenic drugs were generously provided by the manufacturers, namely, sunitinib (Pfizer), pazopanib (GSK), and DC101, the monoclonal antibody targeting mouse VEGFR-2 (ImClone/Eli Lilly). All drugs were prepared according to manufacturer’s specifications. Paclitaxel was dispensed by Sunnybrook Pharmacy Department, Odette Cancer Center (Toronto, Ontario, Canada) at 60 mg/mL and further diluted with normal saline to the appropriate concentration. Control mice received either vehicle and/or normal saline as appropriate. Sunitinib was administered by gavage at 60 mg/kg dose daily for the first 14 days followed by 5 days daily with 2 days break thereafter to reduce toxicity as measured by weight loss. Pazopanib 150 mg/kg was administered by gavage daily without interruption. Paclitaxel was administered intraperitoneally (i.p.) at 50 mg/kg every 3 weeks in the studies, which included combination with DC101 but the dose and schedule was changed to 30 mg/kg once every 2 weeks in studies, which involved combination with sunitinib or pazopanib to minimize toxicity observed in SCID mice (18).

Results and Discussion

We first tested sunitinib on the growth of primary established orthotopic (mammary fat pad) tumors. Cells from the established variant of MDA-MB-231 called LM2.4, which was selected in vivo for aggressive spontaneous metastatic spread after surgical resection of the primary tumor (9) were injected into the mammary fat pad of 6- to 8-week-old female SCID mice, as described previously (9) in Materials and Methods. We did not use a luciferase-tagged clone of LM2.4 (19) because we have found that these cells have a reduced ability for spontaneous metastasis (unpublished observations), the basis of which is currently unknown. When the primary tumors reached a volume of approximately 100 to 150 mm³, sunitinib was administered daily by gavage at a preclinically effective dose of 60 mg/kg, and the treatment continued until end point. As shown in Fig. 1A, a robust growth delay was observed, similar to Abrams and colleagues using another human breast cancer xenograft model (called MX-I; ref. 10). In the case of Abrams and colleagues, this was paralleled by an increase in OS, the extent of which was shown to be further enhanced by combination with chemotherapy, for example, docetaxel (10).

In our case, the mice were sacrificed in this preliminary experiment at an earlier defined endpoint, namely, when the control group tumors reached an average size of approximately 500 mm³ (Fig. 1A). However, in another experiment, shown in Fig. 1B where the primary tumor was surgically resected (at day 20) and the same therapy initiated 3 weeks later (i.e., when the mice have established visceral metastatic disease based on numerous previous studies, e.g., ref. 9 in addition to reproducibility and lack of variability of the short median survival times), no impact of the same treatment on survival was observed. This pattern of discrepancy in outcomes is not specific for sunitinib as we observed a similar pattern using pazopanib (as shown in Fig. 1C and D) where primary tumors in control mice were allowed to grow in this case to endpoint of 1,700 mm³ and the therapy maintained until endpoint.
We next assessed the impact of adding paclitaxel to sunitinib. Shown in Fig. 2A and B is the impact on survival of mice with advanced metastatic disease when maximum tolerated dose (MTD) paclitaxel was combined with sunitinib. Two independent experiments were carried out. If anything, there was a trend to reduced survival in the combination treatment group compared with the mice receiving paclitaxel alone, an observation that is consistent with a phase III breast cancer trial of sunitinib plus another taxane, docetaxel (12), where no added benefit was observed and OS was slightly reduced in the combination treatment group (12). We would note that in the 2 experiments shown in Fig. 2A and B, there was a difference in the therapeutic impact of paclitaxel alone. In one experiment (shown in Fig. 2A) the paclitaxel monotherapy treatment had no statistically significant benefit in median OS, whereas it did in the experiment shown in Fig. 2B. This difference may be due to the more aggressive tumor growth we noted in the experiment shown in Fig. 2A where all of the control mice died by day 60 compared with experiment 2B where all control mice died by day 70. Nevertheless in both experiments, sunitinib did not improve paclitaxel treatment outcomes. We also tested the effect of paclitaxel plus sunitinib in the established primary tumor model (Fig. 2C); sunitinib had a noticeable antitumor effect in contrast to paclitaxel; the 2 drug combination was not significantly different from the sunitinib-treated group.

Figure 1. Differential impact of sunitinib or pazopanib monotherapy on primary breast tumor growth versus postsurgical advanced metastatic breast cancer. Sunitinib administered daily inhibits primary tumor growth (A), but has no survival benefit when treating advanced metastatic disease (B). The bottom shows similar results with pazopanib administered daily (C and D).
As shown in Fig. 3A, DC101 had a robust antitumor effect when used to treat established LM2.4 primary tumors. The paclitaxel treatment, once again, did not have an antitumor effect when used to treat primary tumors. The 2 drug combination was the most effective. However, as shown in Fig. 3B the pattern of response as assessed by survival analysis was somewhat different in the postsurgical advanced metastatic setting. Similar to sunitinib or pazopanib, DC101 was seemingly devoid of activity, at least when used as monotherapy and assessed by its impact on survival, because median survival was 64 to 65 days in both the control and DC101 treatment groups. The paclitaxel monotherapy treatment showed a trend for a survival benefit (from 65 to 78 days) but this did not reach statistical significance. However, median survival was significantly prolonged to 88 days in the combination treatment group compared with control, untreated mice. The difference in median survival between the DC101 + paclitaxel group (88 days) and the paclitaxel group (78 days) was not statistically significant, but would likely have led to a benefit in PFS had we been able to undertake such an assessment, and if so, would mirror the results of the E2100 phase III trial. Taken together, there does seem to be a modest benefit in improving the therapeutic impact of paclitaxel by combination with the VEGF pathway targeting antibody, but not with sunitinib, observations that seem to reflect previous phase III clinical trial results (13, 16), including a head-to-head comparison of
the respective tumor types (lung and pancreatic cancer) in part by using clinically relevant endpoints of tumor response (23). As for PDXs, some recent studies have shown the presence of metastases in clinically relevant patterns in nonresected primary tumor-bearing patient-derived breast cancer xenografts obtained from patients with different breast cancer major subtypes (24), thus making it possible to use these models for preclinical adjuvant and metastatic therapy investigations.

Finally, is there any evidence that an investigational therapy previously shown to be highly effective in the postsurgical preclinical metastatic setting shows prospective clinical activity? In this regard, we have reported that doublet oral metronomic chemotherapy using cyclophosphamide and capecitabine with bevacizumab, with very encouraging results (25). However, as discussed in the Introduction, such phase II trial results have to be confirmed in a larger randomized phase III trial, of which one is underway evaluating metronomic doublet cyclophosphamide and capcitabine with bevacizumab (NCT01131195; www.clinicaltrials.gov). Nevertheless, for now,
our results suggest the value of preclinical modeling post-surgical advanced metastatic disease as a potential strategy to improve how they might predict clinical outcomes. The same may be the case for postsurgical adjuvant therapy models of early stage microscopic (minimal residual) metastatic disease, which can also respond to therapy in a manner different from primary tumors in control experiments (19, 26). Although not practical for routine drug screening, use of such models may be useful to confirm prior preclinical studies using conventional primary tumor therapy models, before embarking on expensive phase II or III metastatic therapy clinical trials.
