Abstract

The established association between inflammatory bowel disease and colorectal cancer underscores the importance of inflammation in colon cancer development. On the basis of evidence that hemostatic proteases are powerful modifiers of both inflammatory pathologies and tumor biology, gene-targeted mice carrying low levels of prothrombin were used to directly test the hypothesis that prothrombin contributes to tumor development in colitis-associated colon cancer (CAC). Remarkably, imposing a modest 50% reduction in circulating prothrombin in fII+/– mice, a level that carries no significant bleeding risk, dramatically decreased adenoma formation following an azoxymethane/dextran sodium sulfate challenge. Similar results were obtained with pharmacologic inhibition of prothrombin expression or inhibition of thrombin proteolytic activity. Detailed longitudinal analyses showed that the role of thrombin in tumor development in CAC was temporally associated with the antecedent inflammatory colitis. However, direct studies of the antecedent colitis showed that mice carrying half-normal prothrombin levels were comparable to control mice in mucosal damage, inflammatory cell infiltration, and associated local cytokine levels. These results suggest that thrombin supports early events coupled to inflammation-mediated tumorigenesis in CAC that are distinct from overall inflammation-induced tissue damage and inflammatory cell trafficking. That thrombin is linked to early events in CAC was strongly inferred by the observation that prothrombin deficiency dramatically reduced the formation of very early, precancerous aberrant crypt foci. Given the importance of inflammation in the development of colon cancer, these studies suggest that therapeutic interventions at the level of hemostatic factors may be an effective means to prevent and/or impede colitis-associated colon cancer progression. Introduction

Multiple studies have suggested that hemostatic factors in general, and the central hemostatic protease thrombin specifically, are major determinants of tumor biology, particularly late-stage processes such as metastasis (1–4). In addition to supporting tumor cell dissemination, thrombin has been suggested to play a role in tumor proliferation and stroma formation (5). However, the contribution of thrombin to tumor growth appears to be perplexingly variable and seemingly context dependent, as the growth of multiple transplantable tumors has been shown to be unaffected in mice with specific deficits in prothrombin or mice lacking selected downstream thrombin targets (e.g., fibrinogen, platelet function, and factor XIII; refs. 1, 3, 6–9). Equally enigmatic is the precise contribution of thrombin and other hemostatic factors to early events leading to cancer development, including tumor cell initiation events and events driving tumor promotion. Previous studies linking tissue factor expression by transformed cells to tumorigenesis infer a role for circulating hemostatic factors in these early events (10, 11), but the role of hemostatic factors downstream of tissue factor in cancer development, if any, remains to be determined. Drawing together the independent evidence that (i) cancer risk is linked to inflammatory processes (12–14), (ii) hemostatic factors control inflammatory events (15–17), and (iii) the malignant phenotype is linked to procoagulant functions (1), an attractive hypothesis is that a major contribution of thrombin to initial tumor development would be most manifest in inflammation-driven cancers. Chronic inflammation is a major risk factor for the development of multiple malignancies, including cancers of the lung, liver, prostate, pancreas, and colon (18). There is equally impressive evidence that thrombin and multiple thrombin substrates drive the inflammatory response in...
Thrombin and CAC
diverse experimental settings (e.g., bacterial infection, arthritis, neuroinflammatory disease; refs. 15–17, 19–21). However, the contribution of thrombin to inflammation-driven cancers, particularly early events involved in tumor development, has never been formally explored. A prime example of the strong association between inflammation and cancer is colitis-associated colon cancer (CAC). Patients with inflammatory bowel disease (IBD) have a 10- to 20-fold increased risk of colon cancer (22). Multiple indirect observations are consistent with the hypothesis that thrombin is a determinant of CAC pathogenesis. Patients with IBD or colon cancer have a significantly increased risk of thromboembolism (23, 24). Elevated biomarkers of hemostatic system activation correlate with a poor response to therapy in colitis and a poor prognosis in colon cancer (25, 26). Epidemiologic studies suggesting that IBD is less common in patients with inherited bleeding disorders infer a role for hemostatic factors in IBD pathogenesis (27). Conversely, other studies have shown a strong correlation between some prothrombotic mutations (e.g., homozygosity for factor VLeiden) and increased colon cancer risk (28). Studies of animal models of colitis and CAC also suggest that hemostatic system components actively contribute to these pathologies. The immunological blockade of tissue factor was shown to diminish colitis-associated inflammation and mucosal damage in mice (29). Fibrinogen-mediated engagement of the leukocyte integrin α5β2 has been shown to drive colitis pathology and support the development and growth of colitis-associated adenosomas (30). While these studies support the view that thrombin contributes to CAC pathogenesis, a direct analysis of the potential contribution(s) of thrombin to thrombin to CAC has never been done.

To directly test the hypothesis that thrombin supports tumor formation in the setting of inflammation-driven colon cancer, comparative analyses of CAC were done in cohorts of control mice and mice with germline- or pharmacologically induced quantitative deficits in prothrombin. We report that a modest decrease in circulating prothrombin (just 50% of normal) dramatically diminished adenoma formation. Interestingly, prothrombin diminution had no obvious impact on the severity of the antecedent colitis. However, lowering circulating prothrombin levels either constitutively or just during the inflammatory phase of the disease prevented the development of aberrant crypt foci and subsequent adenoma formation. These studies suggest that thrombin plays a significant role in very early events involved in tumorigenesis, at least in the context of inflammation-driven carcinogenesis.

Materials and Methods

Transgenic mice

Mice heterozygous for a prothrombin (F2)-null allele (III<sup>+/−</sup>) have been previously described (31, 32). All study group mice were 8- to 12-week-old males that were C57BL/6-inbred at least 6 generations. Wild-type (WT) and III<sup>−/−</sup> mice were generated within the same breeding colony and housed in identical conditions. Study protocols were approved by the Cincinnati Children’s Hospital Institutional Animal Care and Use Committee in accordance with NIH guidelines.

Antisense oligonucleotide-mediated prothrombin depletion and hirudin treatment

Prothrombin synthesis was suppressed in WT C57BL/6 mice using a previously described 20-mer antisense oligonucleotide (ASO) “gapmer” (2). Cohorts were injected subcutaneously with 5 mg/kg III-specific ASO or an equivalent amount of a control irrelevant oligonucleotide of similar chemistry with no significant homology in the mouse transcriptome. Hepatic prothrombin mRNA and plasma prothrombin activity were measured as previously described (31). In separate experiments, 10 mg/kg once daily hirudin (Lepirudin; Baxter) or saline carrier was injected intraperitoneally (i.p.) as specified in the text.

Induction of colitis and colon cancer

CAC was induced as previously described using a single i.p. injection of 10 μg/kg azoxymethane (AOM; Midwest Research Institute, Kansas City, MO) on day 0, followed by two courses of 1.5% dextran sodium sulfate (DSS; days 7–14 and 28–35; ref. 30). Histologic analyses were performed on each lesion dissected, confirming each as an adenoma. Acute colitis was induced using 1.5% DSS (MP Biomedicals) in drinking water for 7 days. Chronic colitis was induced by administering DSS on days 1 to 7 and 21 to 28. Colonic adenosomas were generated without DSS exposure by weekly i.p. injections of 10 μg/kg AOM (33). Here, colons were analyzed 18 weeks after AOM initiation.

Histologic analysis, cytokine measurements, and statistical analyses

Colonic tissue was fixed in Carnoy’s solution and processed for histology. Immunostaining for fibrinogen, proliferating cell nuclear antigen (PCNA), myeloperoxidase (MPO), phosphorylated RelA/p65, and Iba1 was performed essentially as previously described (30, 34). Colonic cytokine concentrations were determined using Luminex technology on a BioPlex analyzer (Bio-Rad) from flash-frozen distal colons homogenized in PBS with a protease inhibitor cocktail (Sigma-Aldrich). Statistical analyses were generated using GraphPad Prism software. Unless otherwise indicated, data shown represent mean with SEM, and P values were generated with a Mann–Whitney U test.

Results

Prothrombin supports adenoma development/ outgrowth in CAC

To test the hypothesis that prothrombin supports tumor development in inflammation-driven cancers, we explored the impact of imposing a simple two-fold diminution in circulating prothrombin on colonic adenoma development in mice with CAC. Cohorts of mice heterozygous for a prothrombin-null allele (III<sup>−/−</sup>) and WT controls were challenged in parallel with AOM/DSS as previously described (29). As expected, evaluation of colonic tissues collected 12 weeks after AOM injection revealed uniform development of adenosomas in all WT mice, most with multiple adenosomas (Fig. 1A). In contrast, III<sup>−/−</sup> mice developed significantly fewer colonic adenosomas (Fig. 1A).
Impressively, a substantial fraction (~30%) of the $fII^{+/−}$ mice enrolled had no discernable adenomas ($P < 0.05$, Fisher exact test), whereas WT mice exhibited 100% phenotypic penetrance of adenoma formation. The data shown represent the combined results of two experiments with similar outcomes.

Although adenoma formation in CAC was significantly reduced in mice carrying low prothrombin levels, lowering prothrombin had no significant impact on clinical metrics associated with the antecedent colitis, such as rectal bleeding and weight loss. We anticipated that the AOM/DSS challenge in $fII^{+/−}$ mice would be easily tolerated with regard to bleeding risk based on prior studies showing that $fII^{+/−}$ mice exhibited plasma coagulation parameters (i.e., PT, aPTT) that were similar to WT mice, never exhibited spontaneous hemorrhagic events, survived well into adulthood, and exhibited tail tip bleeding times comparable to control animals (31). Consistent with these expectations, both WT and $fII^{+/−}$ mice challenged with AOM/DSS developed some DSS-induced rectal hemorrhage, but this was modest and indistinguishable between genotypes. The degree of DSS-induced weight loss was also similar between genotypes. After two courses of DSS, WT mice had lost an average of 4.7% of their body mass (range, −10.3% to +11.5%) compared with a mean loss of body mass of 3.4% (range, −13.1% to +8.2%) in $fII^{+/−}$ mice ($P = 0.7$).

While significantly fewer in number, those adenomas that did form in mice with low prothrombin levels were histologically indistinguishable from those that formed in mice with normal prothrombin levels. The adenomas harvested from both genotypes included a similar spectrum of low- and high-grade lesions (see Fig. 1B and C for representative adenoma histology). Low-grade lesions consisted of thickened mucosa with elongated colonic glands and modest nuclear pleomorphism but no loss of mucosal polarity. High-grade lesions had significant loss of polarity with some glands characterized by piling of epithelial cells (Fig. 1B and C). Colonocytes in these lesions tended to have large vesicular nuclei with nucleoli. Mitotic figures were readily apparent in adenomas harvested from both genotypes and were particularly common in high-grade lesions, regardless of genotype. The adenomas that formed in $fII^{+/−}$ mice were also similar in size to those harvested from control animals. The mean adenoma mass for tumors harvested from WT mice was 15 mg (range, 0.8–130 mg), compared with a mean of 8.9 mg (range, 0.2–39 mg) for tumors harvested from $fII^{+/−}$ mice ($P = 0.4$).

As a complementary approach to explore the role of prothrombin in CAC, hepatic prothrombin expression was pharmacologically reduced using a previously described, highly-selective murine prothrombin ASO “gapmer” (2). Here, cohorts of WT mice received weekly s.c. injections of a prothrombin-specific ASO or an equivalent dose of a biologically irrelevant control oligonucleotide beginning 2 weeks before the initiation of AOM/DSS challenge. This dosing regimen was established to decrease circulating prothrombin levels to about 50% of normal based on quantitation of hepatic mRNA and functional protein assays (Fig. 2A and B). Paralleling our prior observations in mice with germline-based alterations in prothrombin, lowering prothrombin mass for tumors harvested from WT mice was 15 mg (range, 0.8–130 mg), compared with a mean of 8.9 mg (range, 0.2–39 mg) for tumors harvested from $fII^{+/−}$ mice ($P = 0.4$).

![Figure 1. Prothrombin supports colitis-associated adenoma formation. A, quantitation of the total number of adenomas formed per animal after AOM/DSS challenge. Note that mice with a genetically imposed diminution in prothrombin levels to about 50% of normal ($fII^{+/−}$) developed significantly fewer adenomas. Horizontal bars, median values. Shown are representative hematoxylin and eosin-stained sections of adenoma tissue harvested from WT mice (B) and $fII^{+/−}$ mice (C). The high-powered insets show the loss of epithelial cell polarity, nuclear pleomorphism, cell piling (′), and frequent mitotic figures (arrowheads) typical of adenomas. D, a section of unchallenged colonic tissue cut in the same plane is shown for comparison. Size bars, 20 or 10 μm (insets).]
Thrombin and CAC

Figure 2. Pharmacologically decreasing prothrombin (fII) expression significantly limits adenoma formation in CAC. Shown are quantification of hepatic prothrombin mRNA (A) and chromogenic plasma prothrombin activity (B) obtained following 3 weekly doses of prothrombin-specific ASO (5 mg/kg/dose) or a control oligonucleotide, as well as parallel analyses in unchallenged WT and fII–/– mice (C). C, weekly treatment with a prothrombin-specific ASO at this dose significantly limits adenoma formation following AOM/DSS challenge relative to a control, irrelevant oligonucleotide.

Prothrombin, mice treated with prothrombin-specific ASO developed significantly fewer adenomas than control mice challenged in parallel (Fig. 2C). Also paralleling findings in fII–/– mice, ASO-mediated diminution in prothrombin had no discernable effect on the qualitative degree of DSS-induced diarrhea, intestinal bleeding, and weight loss. At the conclusion of the second DSS course, animals treated with a control ASO had lost an average of 23% of their body mass (range, −9% to + 3.4%) and fII ASO–treated mice had lost an average of 1.8% of their body mass (range, −5.1% to + 0.7%, P = 0.8). While adenoma formation was quantitatively reduced in mice treated with the prothrombin-specific ASO, the mass of adenomas harvested in those mice was comparable with those observed in control mice. The mean adenoma mass for tumors harvested from control mice was 5 mg (range, 0.1–62.1 mg), compared with a mean of 5.9 mg (range, 0.1–27.1 mg) for adenomas harvested from fII ASO–treated mice (P = 0.7). The histologic features of adenomas were also similar between cohorts treated with a control oligonucleotide or fII ASO and indistinguishable from those harvested from WT and fII–/– mice in separate experiments (data not shown). These results reveal that prothrombin constitutes a seminal determinant of tumor development/outgrowth in the setting of colitis-associated cancer. However, lowering prothrombin did not appreciably influence the features of adenomas, once developed, including overall growth and histologic features.

Decreasing circulating prothrombin does not significantly alter mucosal damage, inflammatory cell accumulation, or local cytokine production in DSS-induced colitis

Previous studies have shown that thrombin and multiple thrombin targets (e.g., PARs, fibrinogen, factor XIII, protein C, and osteopontin) are coupled to the inflammatory response in several experimental settings (15–17, 19–21). To determine whether a modest decrease in circulating prothrombin influences the severity of DSS-induced colitis, we challenged cohorts of fII–/– mice and controls in parallel with a single 7-day course of DSS. Consistent with observations in mice challenged with AOM and multicourse DSS, the degree of diarrhea and rectal bleeding observed in fII–/– mice was qualitatively similar to that observed in WT mice, as was the degree of weight loss. WT mice lost an average of 10.8% of their body mass (range, −27.6% to + 6.1%) compared with a mean loss of body mass of 11.7% (range, −25.7% to −3.0%) in fII–/– mice (P = 0.9). Histologic analyses of colonic tissue harvested immediately after 7 days of DSS exposure revealed significant areas of inflammatory cell infiltration, edema, crypt loss, and ulceration that were similar between genotypes (Fig. 3A). As expected, analyses of colons harvested from unchallenged WT and fII–/– mice (i.e., proximal to any DSS challenge) appeared normal and indistinguishable (Fig. 3A). Detailed comparisons of colonic tissue using an established multiparameter semiquantitative histologic analysis of DSS-induced colitis severity did not reveal any significant differences between genotypes in any of the parameters assessed, including the degree of edema, crypt loss, ulceration, and inflammatory cell infiltration (Fig. 3B). Similar results were obtained in complementary comparisons of colitis severity following 7 days of DSS exposure in cohorts of mice treated with either a prothrombin-specific ASO or a control oligonucleotide (see Supplementary Material).

Immunohistochemical staining of colons for fibrinogen deposition showed qualitatively similar degrees of fibrinogen deposition in colons harvested from WT and fII–/– mice following 7 days of DSS exposure. Fibrinogen deposits were primarily associated with areas of significant mucosal edema (Fig. 3C). The inflammatory infiltrates present in DSS-challenged colons were primarily composed of macrophages and neutrophils. Immunostaining for myeloperoxidase (neutrophils) and Iba1 (macrophages) revealed similar degrees of infiltration with both these cell types in DSS-challenged WT and fII–/– mice (Fig. 3C). Consistent with these more qualitative histologic findings, separate quantitative comparisons of local cytokines previously shown to drive colitis and CAC (TNFα, interleukin
[IL-6, KC, IFNγ, and IL-1β; refs. 35, 36] in colonic homogenates harvested from WT and fII+/− mice immediately following 7 days of DSS exposure were similar between genotypes (Fig. 3D). Analyses of local cytokines in colonic homogenates from prothrombin-specific ASO and control oligonucleotide–treated mice following 7 days of DSS also showed no significant differences associated with lowering prothrombin levels to about 50% of normal (see Supplementary Material).

To determine whether decreasing prothrombin levels affects the degree of mucosal damage and inflammatory cell infiltration associated with multicourse DSS exposure, we challenged WT and fII+/− mice with two courses of DSS...
and terminated at the time of withdrawal of the second DSS early (i.e., 1 week before initiation of the AOM/DSS challenge). Edematous suppression of prothrombin levels was imposed either by daily injections of hirudin, a highly specific, albeit short-lived, thrombin inhibitor, or by continuous ASO treatment. Here, mice receiving daily i.p. injections of the highly specific, albeit short-lived, thrombin inhibitor, hirudin, during this early timeframe developed significantly fewer adenomas than saline vehicle-treated mice challenged in parallel (Fig. 5B). Consistent with findings in mice with low prothrombin levels, daily hirudin treatment had no significant effect on the degree of colonic mucosal damage or inflammatory cell infiltration observed following 7 days of DSS exposure (Fig. 5C).

In contrast to the significant diminution in adenoma formation observed when selectively limiting prothrombin expression or thrombin catalytic activity during the early effector phase characterized by epithelial damage and colitis, the same interventions later in disease pathogenesis had no significant impact on adenoma formation. Here, ASO-mediated suppression of circulating prothrombin to half-normal starting 1 week after the withdrawal of the second DSS course (i.e., day 42) and continuing until sacrifice (i.e., day 84) had no significant effect on adenoma formation (Fig. 5D). Similarly,

Figure 4. Prothrombin deficiency does not significantly alter the clinical severity or mucosal damage associated with multicourse DSS challenge. A, waxing and waning weight loss associated with multicourse DSS challenge is similar in WT and flt<sup>−/−</sup> mice (n = 9 per group). B, photomicrographs of representative hematoxylin and eosin-stained sections of colonic tissue harvested from WT and flt<sup>−/−</sup> mice at the end of the second course of DSS (i.e., day 28). Note that DSS-challenged colons from mice of both genotypes revealed similar degrees of significant mucosal ulcerations (arrows) and inflammatory edema (†). Size bars, 50 μm. C, detailed microscopic analyses using a multiparameter histopathologic scoring system confirmed that DSS-challenged colons harvested from WT mice (n = 8) and flt<sup>−/−</sup> mice (n = 9) showed similar degrees of disease severity for each parameter analyzed. *P < 0.05 as compared to WT mice (n = 9) for each comparison between DSS-challenged WT and flt<sup>−/−</sup> cohorts.

Thrombin and CAC

Thrombin promotes adenoma formation/outgrowth in CAC primarily through mechanisms temporally associated with and dependent on inflammatory colitis

To determine whether the impact of thrombin on adenoma development/outgrowth is formally dependent on the antecedent colitis, we explored whether a modest reduction in prothrombin expression would limit adenoma formation in an experimental setting not driven by overt inflammation. Here, we induced adenomas in flt<sup>−/−</sup>/ and WT mice in parallel using an established protocol consisting of 6 weekly doses of AOM without DSS exposure. Contrasting experiments where adenoma formation was dependent on DSS-induced colitis, the decrease in prothrombin expression conferred by the flt<sup>−/−</sup> genotype had no effect on the number of adenomas formed after multicourse AOM (Fig. 5A). Collectively, these results suggest that although limiting prothrombin does not overtly alter initial tissue damage and secondary inflammatory cell infiltration in AOM/DSS-challenged mice, the contribution of prothrombin to adenoma formation appears to be dependent on an inflammatory microenvironment.

To better define when in the course of disease pathogenesis prothrombin sufficiency is vital to adenoma development in CAC, 2 experimental designs were used whereby ASO-mediated suppression of prothrombin levels was imposed either early (i.e., 1 week before initiation of the AOM/DSS challenge and terminated at the time of withdrawal of the second DSS course; see Fig. 5B) or late (i.e., 1 week after the withdrawal of the second DSS course and continued until the time of sacrifice 12 weeks post-AOM initiation; see Fig. 5D). Weekly s.c. injections of prothrombin-specific ASO were given to reduce and subsequently maintain circulating prothrombin at approximately half-normal (the new steady state approached within about 5 days of initiating ASO based on the prothrombin half-life of ~60 hours). Lowering prothrombin levels during the early phase of disease pathogenesis resulted in a major reduction in the number of adenomas formed 12 weeks after AOM injection (Fig. 5B), paralleling previous results observed in flt<sup>−/−</sup> mice and mice receiving continuous ASO treatment. Also paralleling previous results, the adenomas that did form in mice with low prothrombin levels were similar in size and histologically indistinguishable from those that formed in mice with normal prothrombin levels (data not shown). Similar results were obtained when AOM/DSS challenged mice were treated with a protein-level inhibitor of thrombin proteolytic activity during the antecedent DSS-induced colitis (days 7 through 35). Here, mice receiving daily i.p. injections of the highly specific, albeit short-lived, thrombin inhibitor, hirudin, during this early timeframe developed significantly fewer adenomas than saline vehicle-treated mice challenged in parallel (Fig. 5B). Consistent with findings in mice with low prothrombin levels, daily hirudin treatment had no significant effect on the degree of colonic mucosal damage or inflammatory cell infiltration observed following 7 days of DSS exposure (Fig. 5C).
daily hirudin treatment initiated immediately after completion of the second DSS course (i.e., day 35) and continuing until sacrifice did not significantly affect adenoma formation (Fig. 5D). Taken together, these results suggest that the decrease in colitis-induced adenomas observed in mice with diminished circulating prothrombin is due to a direct action of thrombin-mediated proteolysis that is most relevant during the inflammatory phase of the disease process.

**Prothrombin promotes tumorigenesis in CAC**

To directly determine whether prothrombin supports early transformation events preceding gross tumor outgrowth in CAC, we analyzed colonic tissue harvested from AOM/DSS-challenged mice treated with prothrombin-specific ASO or control oligonucleotide just 1 week after withdrawal of the second course of DSS (i.e., day 42). While the degree of residual mucosal damage and local inflammatory markers (see Supplementary Material) at this early time point were not significantly affected by diminished prothrombin levels, there were four-fold fewer aberrant crypt foci (ACF) within colonic epithelium harvested from prothrombin ASO–treated animals relative to control mice (Fig. 6A). These foci exhibited complex glandular structure with tortuous, branched lumens. The epithelial cells in these lesions showed loss of polarity with mitotic figures and nuclear atypia, including vesicular chromatin and nucleoli (Fig. 6B). In contrast, the mucosa of colons harvested from mice with an ASO-mediated decrease in prothrombin expression was generally normal in appearance with significantly fewer ACF (Fig. 6B). However, the few abnormal lesions that were present in this cohort were histologically indistinguishable from those observed in colons harvested from mice with normal prothrombin levels (Fig. 6C). A separate independent analysis of identical experimental design was completed with similar results.
Immunohistochemical staining of colonic tissue harvested from mice with normal and low prothrombin levels 1 week after withdrawal of the second DSS course revealed significant fibrin(ogen) deposition associated with ACF (Fig. 6B). The ACF that were observed in mice with low prothrombin levels, although significantly fewer in number, exhibited fibrin(ogen) deposits comparable to those observed in ACF seen in control mice (Fig. 6B). Fibrin(ogen) deposition was rarely observed in areas of normal-appearing colonic tissue, which predominated in mice with low prothrombin levels. Comparisons of apoptotic cells in these same tissues performed using a cleaved caspase-3 antibody revealed a similar degree of cellular apoptosis in cohorts with normal and low prothrombin levels (data not shown). Apoptotic nuclei were noted in superficial epithelial cells in intact appearing crypts and occasionally in ACF, regardless of prothrombin ASO treatment. Immunohistochemical staining for the marker of cellular proliferation, PCNA, revealed strongly positive nuclear staining in epithelial cells in ACF (Fig. 6B). While the overall number of PCNA-positive cells was lower in prothrombin ASO–treated mice, this was a function of the fewer total ACF in this cohort. The ACF that did form in prothrombin ASO–treated animals were generally composed of epithelial cells strongly positive for nuclear PCNA and histologically similar to ACF observed in control mice (Fig. 6B). The more normal appearing colonic mucosa had only a few PCNA-positive cells localized in the base of the colonic crypts, a pattern consistent with normal and/or healing mucosa (Fig. 6B). Immunohistochemical staining for phosphorylated RelA/p65, a marker of NF-κB activation, revealed a similar degree of positive staining cells in ACF, regardless of prothrombin levels (data not shown). Cells staining positive for this marker were uncommon in normal-appearing crypts. However, detailed quantitation of phosphorylated RelA/p65 staining cells in intact, properly oriented crypts present within multiple random microscope fields for each mouse. Each data point represents one field and approximately six 40× fields were assessed per animal. Size bars, 50 μm.

**Discussion**

These studies establish, for the first time, that thrombin can play a key role in the development of precancerous lesions and subsequent tumor formation in the context of inflammation-driven colon cancer. Taken together with prior reports showing that pro/thrombin is critical to metastasis in vivo (1, 2, 4, 8, 37, 38), these studies show that this central hemostatic protease can drive both tumorigenesis and tumor dissemination. A remarkable facet of these studies was the finding that even a very modest 50% reduction in circulating prothrombin, imposing no significant bleeding risk (31), was sufficient to dramatically decrease tumor formation in CAC. Thrombin-mediated proteolysis was important in driving adenoma formation during the early, initiating phase of mucosal inflammation-associated tumorigenesis, although a modest reduction in thrombin activity affected neither the overall severity of mucosal damage nor the accumulation of inflammatory cells and associated cytokines following DSS challenge. Nevertheless, these studies demonstrate that inflammatory processes...
underlie the mechanism linking thrombin and adenoma formation, as decreasing prothrombin levels had no effect on colonic adenoma formation elicited by repeated carcinogen exposure in the absence of investigator-imposed inflammation. Together these results suggest that thrombin supports colitis-associated adenoma formation by regulating local inflammatory cell functions and/or epithelial cell responses to inflammation rather than altering overall tissue damage or inflammatory cell trafficking. Although the mechanistic details remain to be fully resolved, it is clear that prothrombin constitutes an important, but never previously appreciated, modulator of early events in CAC and that modest interventions at the level of prothrombin can dramatically reduce the formation of precancerous lesions and subsequent adenoma formation.

The finding that thrombin promotes tumorigenesis in CAC through mechanisms that appear to depend on antecedent inflammation raises the possibility that thrombin-mediated events alter inflammatory functions in ways that are important for tumorigenesis but do not significantly affect inflammatory cell accumulation or mucosal damage. The local elaboration of inflammatory products has been suggested to directly support the progression of CAC through several independent mechanisms. For example, the local release of cytokines and growth factors has been proposed to support the survival and proliferation of premalignant and transformed cells (12, 18, 35, 39, 40). A separate attractive concept is that the local release of potentially mutagenic reactive oxygen and nitrogen species increases the risk of transforming mutations and proliferation of premalignant and transformed cells (12, 18, 35, 39, 40). A separate attractive concept is that the local elaboration of reactive oxygen and nitrogen species (ROS) production, elaboration of proteases, production of key cytokines relative to mice expressing WT fibrinogen (30). Therefore, fibrin(ogen)-mediated engagement promotes early inflammatory events in colitis that are coupled to the later development of adenomas. Given the critical importance of fibrinogen (46) in tumorigenesis in the context of CAC, it is possible that even a modest decrease in local fibrin polymer formation stemming from lowered prothrombin expression, one that would not necessarily be detectable by immunostaining, could limit events crucial for tumorigenesis in this setting. It is also possible that modestly decreasing prothrombin expression limits fibrin polymer formation during a narrow, but critically important, period in tumorigenesis in CAC that ultimately limits adenoma formation. Of course, the fact that our analyses of experimental colitis in mice with lowered prothrombin expression did not precisely phenocopy analyses in mice with alterations in fibrinogen also raises the possibility that thrombin promotes tumorigenesis in CAC through mechanisms independent of fibrin polymerization.

Another model compatible with the data showing that thrombin drives tumorigenesis in CAC is that thrombin-mediated signaling events within tumor cell precursors dependent on an inflammatory milieu support tumorigenesis, but these events do not fundamentally alter mucosal damage or inflammatory events. In this regard, signaling through the thrombin-activatable receptor, PAR-1, could directly influence cell-intrinsic properties important in early tumor development (5, 37). Intestinal epithelial cells have been shown to upregulate PAR-1 expression during times of cellular stress, such as inflammatory colitis (46). Previous studies have suggested that tumor cell-associated PAR-1 activation supports tumor cell proliferation and limits apoptosis (5, 37). Studies showing that PAR-1 is dispensable for tumorigenesis in the context of oncogene-driven breast cancer in mice demonstrate that this thrombin receptor is not critically required for tumorigenesis (47). However, the role of PAR-1 in tumorigenesis has not been
investigated in the setting of nonsterile, inflammation-associated cancer such as CAC, in which any survival/proliferative advantage conferred by PAR-1 signaling in epithelial cells could be a decisive factor in tumor formation. Dissecting the precise contribution, if any, of thrombin-mediated PAR-1 activation to colonic epithelial cell transformational changes is complicated by the fact that this receptor is expressed on numerous cell types capable of influencing CAC pathogenesis through distinct, and potentially opposing, mechanisms. In fact, constitutional PAR-1 deletion was shown to augment the inflammatory response and subsequent inflammatory damage in experimental colitis mediated by local ozaenal administration as well as Helicobacter pylori-driven gastritis (42, 43), suggesting that PAR-1 activation has an anti-inflammatory role in colitis. It remains to be resolved whether PAR-1 signaling in colonic epithelia underlies the present finding of diminished colonic adenoma formation in low prothrombin mice following CAC challenge. Specifically determining whether colonic epithelial cell-associated PAR-1, or other PAR-1-expressing cellular compartments in the colon, plays a role in tumor formation in CAC would require the ability to manipulate PAR-1 expression in a cell-type-specific fashion.

The data presented here reveal a role for thrombin in tumorigenesis in the context of colitis-driven colon cancer. However, it is conceivable that hemostatic factors may also play a role in the pathogenesis of colon cancer in contexts not associated with overt colitis. Clinical studies have shown that persistent elevation of markers of hemostatic system activation (i.e., elevated plasma levels of prothrombin fragment 1 and fibrinopeptide A) as well as certain prothrombotic risk factors (i.e., factor V Leiden) are coupled to a significantly increased risk of developing cancers of the digestive tract (28, 48, 49), suggesting that thrombin generation promotes the development of spontaneous colorectal cancer. Emerging evidence suggests that commensal bacteria as well as dietary and host factors (e.g., obesity) regulate the mucosal immune microenvironment and may influence colon cancer pathogenesis (36). Similarly, it is possible that thrombin mediates highly localized inflammatory events affecting immune and/or epithelial cell types that could play a broad role in colon cancer pathogenesis. Although lowering prothrombin did not affect adenoma formation following multicourse AOM exposure, this approach may not model all aspects of the complex genetic and environmental/immunological factors that lead to spontaneous colon cancer in humans (50).

In summary, these studies clearly indicate that the role of thrombin in cancer pathogenesis is not limited to late events, such as metastasis. Thrombin can also strongly influence tumorigenesis in the context of inflammation-driven colon cancer. Given that inflammation has been strongly implicated in the development of multiple malignancies (e.g., cervical, lung, gastric, ovarian, and prostate cancers; refs. 12–14), it is possible that the importance of thrombin in tumor development is not limited to colon cancer. These studies also imply that therapies designed to limit prothrombin expression or thrombin function may represent attractive options for preventing colon cancer in high-risk individuals without bleeding risk.

Disclosure of Potential Conflicts of Interest

E.S. Mullins is a consultant/advisory board member of Baxter Healthcare. No potential conflicts of interest were disclosed by the other authors.

Authors’ Contributions

Conception and design: M.J. Flick, J.S. Palumbo
Development of methodology: W. Miller, L. Rosenfeldt, M.J. Flick, E.S. Mullins, A. Revenko, J.S. Palumbo
Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.): B. Turpin, W. Miller, L. Rosenfeldt, K. Kombrinck, K.A. Steinbrecher, E. Harmel-Laws, E.S. Mullins, M. Shaw, D.P. Witte, J.S. Palumbo
Analysis and interpretation of data (e.g., statistical analysis, biostatistics, computational analysis): B. Turpin, W. Miller, K.A. Steinbrecher, J.S. Palumbo
Writing, review, and/or revision of the manuscript: B. Turpin, W. Miller, L. Rosenfeldt, M.J. Flick, K.A. Steinbrecher, E.S. Mullins, D.P. Witte, A. Revenko, B. Monia, J.S. Palumbo
Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases): W. Miller, L. Rosenfeldt, E. Harmel-Laws, E.S. Mullins
Study supervision: J.S. Palumbo

Acknowledgments

The authors thank Dr Jay L. Degen for critically reviewing the article.

Grant Support

This work was supported by the NIH grant R01-HL085545 and a grant from the American Society of Hematology. The costs of publication of this article were defrayed in part by the payment of page charges. This article must therefore be hereby marked advertisement in accordance with 18 U.S.C. Section 1734 solely to indicate this fact.

Received November 18, 2013; revised February 19, 2014; accepted March 11, 2014; published OnlineFirst April 7, 2014.
