Abstract

Members of the Angiopoietin family regulate various aspects of physiological and pathological angiogenesis. While Angiopoietin-1 (Ang-1) decreases endothelial cell permeability and increases vascular stabilization via recruitment of pericytes and smooth muscle cells to growing blood vessels, Angiopoietin-2 (Ang-2) mediates angiogenic sprouting and vascular regression. In this study, we used the Rip1Tag2 transgenic mouse model of pancreatic β-cell carcinogenesis to investigate the roles of Ang-1 and Ang-2 in tumor angiogenesis and tumor progression. On their own, transgenic expression of human Ang-1 or Ang-2 in pancreatic β-cells caused formation of peri-insular lymphatic vessels in the absence of effects on blood vessel density, islet morphology or physiology. When crossed to Rip1Tag2 mice, both Ang-1 and Ang-2 expressing β-cell tumors showed increased peri-tumoral lymphangiogenesis in the absence of metastasis to local lymph nodes or distant organs. There was no alteration in tumor outgrowth, blood vessel density or vessel maturation in Ang-1-expressing tumors. In contrast, Ang-2-expressing tumors exhibited diminished pericyte recruitment to blood vessels that were dilated, non-functional and highly permeable. These tumors were hemorrhagic, highly infiltrated by leukocytes and impaired in outgrowth. Together, our findings establish that Ang-2 antagonizes Ang-1 function, leading to excessive vessel sprouting with impaired pericyte recruitment and vessel stabilization. The poor perfusion of immature blood vessels results into retarded tumor growth, defining an important pathophysiological pathway required for efficient tumorigenesis.

Précis:

Findings assess the functional contribution of Angiopoietin family members to tumor angiogenesis and suggest that it is their relative ratio that guides vascular growth.
Introduction

The transition from pre-vascular hyperplasia to highly vascularized, outgrowing tumors is referred to as the “angiogenic switch” (1). The requirement of active angiogenesis for tumor outgrowth has been repeatedly demonstrated, for example by depletion of angiogenic growth factors or by the specific targeting of the activities of their receptors (2-4). Many factors are involved in inducing tumor angiogenesis and, among them, members of the Vascular Endothelial Growth Factor (VEGF) family, Fibroblast Growth Factors (FGFs), and several others have been extensively studied (2-4). By binding to their cognate receptor Tie-2, angiopoietins (Ang) have also been shown to exert critical roles during physiological angiogenesis and tumor angiogenesis. The family includes four ligands (Ang-1 to 4) and two corresponding tyrosine kinase receptors (Tie-1 and Tie-2) (5,6). While Ang-3 and 4, diverging gene counterparts of mice and human, respectively, are still poorly understood, Ang-1 and Ang-2 have been intensely studied. Both specifically bind Tie-2 receptor with comparable affinities (7). However, while Ang-1 is an agonist of Tie-2 receptor signaling, in most circumstances Ang-2 exerts an antagonistic function. Ang-1 is predominantly expressed by mesenchymal cells and acts in a paracrine manner by binding Tie-2 receptors expressed on endothelial cells. Ang-1-mediated Tie-2 activation promotes vessel assembly and maturation by mediating survival signals for endothelial cells and by stimulating the recruitment of mural cells (8). Ang-1-mediated vessel stabilization can be seen as vessel normalization (9).

In contrast, Ang-2 is mainly produced by endothelial cells and stored in Weibel-Palade bodies from where it is released by activating cues and acts as an autocrine antagonist of Ang-1-mediated Tie-2 activation (6,10). Ang-2 thereby primes and activates vascular endothelium to respond to other angiogenic factors, such as VEGF, and induces vascular destabilization but also vascular sprouting and branching. However, Ang-2 has also been reported to activate Tie-2 signaling, yet the molecular basis for its dual function is not fully understood (11,12).
expression of Ang-2 in different tumor cell lines has also resulted in varying outcomes: it either enhanced the growth of hypervascular, often more invasive tumors (13-16) or it suppressed tumor growth by disrupting adequate tumor angiogenesis and vessel maturation (17). On the other hand, tumor growth is impaired in Ang-2-deficient mice (18).

The roles of Ang-1 and Ang-2 in tumor angiogenesis and tumor outgrowth have not been directly compared in stochastically growing tumors. Here, we have employed the Rip1Tag2 transgenic mouse model of pancreatic β-cell carcinogenesis to force the expression of Ang-1 and Ang-2 during multistage tumor development. In Rip1Tag2 transgenic mice, SV40 large T antigen (Tag) is expressed under the control of the rat insulin promoter (Rip1) specifically in the insulin-producing β-cells of pancreatic islets of Langerhans (19). Several tumor stages can be distinguished, including β-cell hyperplasia, angiogenic dysplasia, adenoma, and carcinoma (20,21). One of the factors inducing angiogenesis in tumors of Rip1Tag2 mice is VEGF-A. It is secreted by β-tumor cells, and matrix-associated VEGF-A is released by matrix metalloproteinase-9 (MMP-9) concomitantly with the onset of angiogenesis (22). Consistent with these findings, inhibition of VEGF-A or MMP function represses tumor angiogenesis (23-25).

To assess the functional contribution of Ang-1 and Ang-2 to tumor angiogenesis, we have generated transgenic mouse lines, where either human Ang-1 (hAng-1) or human Ang-2 (hAng-2) are expressed under the control of the Rip1 promoter (Rip1Ang-1 or Rip1Ang-2). Rip1Ang-1 or Rip1Ang-2 mice were then crossed with Rip1Tag2 mice. Transgenic expression of both Ang-1 and Ang-2 led to the formation of lymphatic vessels around islets of Langerhans and β-cell tumors. While Ang-1 only marginally increased blood vessel maturation and tumor growth, the expression of Ang-2 led to increased numbers of infiltrating leukocytes, elevated levels of VEGF-A expression, aberrant tumor angiogenesis and, with it, retarded
tumor growth.

Material and Methods

**Mice**

The generation of Rip1Ang-1 and Rip1Ang-2 single-transgenic mice and of Rip1Tag2;Rip1Ang-1 and Rip1Tag2;Rip1Ang-2 double-transgenic mice is described in Supplemental Material. Rip1Tag2;Rip1Ang-1 and Rip1Tag2;Rip1Ang-2 and Rip1Tag2 littermate control mice were sacrificed between 12 and 13 weeks of age. PTK787/ZK222584 (PTK/ZK) was kindly provided by Novartis Pharma, Basel, Switzerland. 12 weeks old Rip1Tag2 or Rip1Tag2;Rip1Ang-2 mice were treated with either 100 mg/kg bodyweight PTK/ZK dissolved in polyethylene glycol 300 (PEG-300; Sigma-Aldrich) or PEG-300 alone by daily oral administration for 5 days. All experimental procedures involving mice were performed according to the guidelines of the Swiss Federal Veterinary Office (SFVO) and the regulations of the Cantonal Veterinary Office of Basel Stadt.

**Histopathological analysis**

Processing of tissues for histological analysis is described in Supplemental Material. Histologic analysis and immunostaining was done on paraffin sections (5 μm) or on cryosections (7 μm) as previously described (26,27). For three-dimensional confocal reconstruction images, pancreatic cryosections (80-100 μm) were used (28). Antibodies used are described in Supplemental Material. CD31+ intra-tumoral endothelial cells and CD45+, F4/80+, 7/4+, pH3+ or caspase-3+ cells in the tumors were determined using Image J software (National Institute of Mental Health, Bethesda, MD, USA). Histological staging and grading of tumors was performed as described (20).
**Lectin perfusion**

For the analysis of functional blood vessels, mice were tail vein-injected with 100 μl of 1 mg/ml fluorescein-labeled *Lycopersicon esculentum* lectin (FL-1171, Vector Laboratories, Buringame, CA, USA) under i.p. anesthesia with Nembutal Sodium Solution (Abbott Laboratories, North Chicago, IL, USA). After 5 min, mice were heart perfused with 10 ml of 4% PFA followed by 10 ml PBS. Isolated pancreata were immersed in ascending concentrations of sucrose (12%, 15%, and 18% for 1 h each at +4°C) overnight and embedded in OCT.

**Cell lines**

Human Umbilical Vein Endothelial Cells (HUVEC) were purchased from ATCC (Washington, DC, USA) and used at low passage numbers and without further authentication for the collagen gel assay described in Suppl. Methods.

**Statistical analyses**

Statistical analysis was performed using GraphPad Prism software (GraphPad Software Inc., San Diego, USA).

**Results**

*Transgenic expression of human Ang-1 and Ang-2*

Quantitative reverse transcription-PCR (qRT-PCR) and immunoblotting analysis revealed that endogenous mouse Ang-1 and Ang-2 were expressed at low levels in the β-cells of pancreatic islets of Langerhans or in tumors of Rip1Tag2 (RT2) mice (Suppl. Figures 1, 2A). To assess whether angiopoietins could have a role in tumor angiogenesis in Rip1Tag2 mice we targeted expression of human Ang-
1 (hAng-1) and human Ang-2 (hAng-2) to the β-cells of pancreatic islets of Langerhans. cDNA fragments encoding hAng-1 and hAng-2, fused in frame at their 5’ ends with a signal peptide and a 10-amino acid Myc-tag were cloned between the rat insulin II gene promoter fragment Rip1 (19) and a SV40 polyadenylation site (27) (Suppl. Figure 2B). Seven Rip1Ang-1 and six Rip1Ang-2 founder lines were analyzed for transgene expression by RT-PCR, immunoblotting and immunofluorescence microscopy using specific antibodies against human angiopoietins and against myc-tag. Three founder lines each exhibited specific expression of correct size human Ang-1 and human Ang-2, respectively, in pancreatic β-cells (Figure 1, Suppl. Figures 1, 2A, 3). No expression of the transgenes was detected in islets of wild-type littermate mice. Two founder lines each of Rip1Ang-1 (RA-1) and Rip1Ang-2 (RA-2) exhibited homogenous expression of hAng-1 and hAng-2, respectively, in all β-cells of individual islets of Langerhans and were used for further experimentation.

**Peri-insular lymphangiogenesis in RA-1 and RA-2 transgenic mice**

Histopathological analysis of pancreata of RA-1 and RA-2 mice did not reveal any changes in the numbers or morphology of islets as compared to non-transgenic littermate mice. The ratio and localization of endocrine α and β-cells within individual islets of Langerhans as well as fasting blood glucose levels were unaffected in RA-1 and RA-2 mice (data not shown). Immunofluorescence staining with antibodies against the endothelial cell surface marker CD31 revealed that neither the expression of Ang-1 nor of Ang-2 did significantly change blood vessel morphology or density in islets of transgenic mice as compared to non-transgenic controls (Suppl. Figure 4A, B).

However, staining of pancreatic sections with antibodies against the lymphatic endothelial cell marker LYVE-1 revealed a significant increase in the density of lymphatic vessels in the periphery of islets of RA-1 and RA-2 mice as compared to
non-transgenic controls (Figure 2A, B). These results indicate that both Ang-1 and Ang-2 are able to induce lymphangiogenesis, an observation consistent with previous reports that mice deficient in Ang-2 expression exhibit defects in lymphangiogenesis and that Ang-1 is capable of inducing lymphatic sprouting and hyperplasia (29-31).

Ang-1 and Ang-2 affect tumor growth

To assess the role of Ang-1 and Ang-2 in tumorigenesis, RA-1 and RA-2 transgenic mice were crossed with Rip1Tag2 (RT2) mice. The resulting RT2 single-transgenic mice and Rip1Tag2;Rip1Ang-1 (RTRA-1) or Rip1Tag2;Rip1Ang-2 (RTRA-2) double-transgenic mice were sacrificed between 12 and 13 weeks of age, when these mice succumb to hypoglycemia caused by excessive tumoral insulin production. Immunofluorescence and immunoblotting analysis revealed that in RTRA-1 and RTRA-2 double-transgenic mice most β-tumor cells expressed human Ang-1 and Ang-2, respectively (Suppl. Figures 2B, 5, 6), yet human or mouse angiopoietins were not detectable by ELISA in the serum of these mice (data not shown).

Tumor growth in RTRA-1 mice was moderately, yet not significantly increased as compared to single-transgenic RT2 littermates (Figure 3A). Histological analysis of tumor progression revealed that the numbers of normal and hyperplastic islets, adenomas and carcinomas were unchanged (Figure 3A). In contrast, RTRA-2 mice displayed a significant reduction in tumor volumes (Figure 3B) and in the numbers of tumors per mouse (3.64 ± 0.33 for RTRA-2 vs. 5.48 ± 0.35 for RT2). Furthermore, the fraction of hyperplastic islets and adenomas increased, whereas carcinomas were decreased in RTRA-2 mice (Figure 3B). Stainings with antibodies against insulin on histological sections of pancreas, liver and lung did not reveal any metastasis in lymph nodes and lung (Suppl. Figure 7A), while micrometastasis detectable in the livers of these mice was not affected by the transgenic expression of Ang-1 and Ang-2, respectively (Suppl. Figure 7B).
Concomitant with the increased and reduced tumor growth in RTRA-1 and in RTRA-2 mice, respectively, the numbers of proliferating, phosphohistone-3-positive β-tumor cells were significantly increased in RTRA-1 and significantly decreased in RTRA-2 mice (Figure 3A, B). In addition, analysis of apoptosis by staining for cleaved caspase-3 revealed a significant reduction in the number of apoptotic cells within the tumors of RTRA-1 and a significant increase in RTRA-2 mice (Figure 3A, B).

**Aberrant tumor angiogenesis in RTRA-2 mice**

The slight increase and the significant decrease of tumor outgrowth in RTRA-1 and in RTRA-2 mice, respectively, may be based on alterations in tumor-induced angiogenesis. Immunofluorescence staining for CD31 revealed no differences in the number of intra-tumoral blood vessels in RTRA-1 as compared to tumors from RT2 mice (Figure 4A). To further examine the functionality of blood vessels, the various genotype mice were injected i.v. with fluorescein-labeled *Lycopersicon esculentum* lectin to visualize vessel perfusion and morphology. The tumor blood vessels in RTRA-1 and in RT2 control mice were fully perfused (Figure 4A, Figure 5A). In contrast, in RTRA-2 mice intra-tumoral blood vessels and endothelial cells were significantly increased in numbers, yet appeared dilated and disorganized, and their perfusion was dramatically impaired (Figure 4B, Figure 5A). Pericyte coverage as one hallmark of capillary maturation was analyzed by immunofluorescence staining with antibodies against NG2 and CD31 for pericytes and endothelial cells, respectively (Figure 5B). In RTRA-1, pericyte density and the percentage of tumor blood vessels covered with pericytes did not differ from RT2 controls (Figure 4A, Figure 5B). However in RTRA-2 mice, overall pericyte density was slightly diminished and pericyte-blood vessel coverage was significantly decreased as compared to RT2 control mice (Figure 4B, Figure 5B). Three-dimensional reconstruction of laser scanning confocal microscopical images confirmed the intimate connection of pericytes with endothelial cells in RT2 and RTRA-1 mice and the disruption of these
interactions in RTRA-2 mice (Figure 5B).

To investigate whether Ang-1 or Ang-2 exerted a direct pro-angiogenic function, we co-cultured isolated dysplastic islets in a collagen matrix together with human umbilical vein endothelial cells (HUVEC). In this assay, angiogenic dysplastic islets derived from RT2 mice induce HUVEC migration, proliferation and tube formation, whereas non-angiogenic islets fail to do so (21, 27). In this assay, islets from 9 weeks old RT2, RTRA-1 and RTRA-2 mice did not show any significant difference in their angiogenic activities (Suppl. Figure 8A-C).

Next, we assessed which cell types of the various genotype tumors expressed the receptor for angiopoietins. RT-PCR analysis revealed that Tie-2 is expressed mainly by CD31+ endothelial cells (BEC) and not by glucagon-like peptide receptor 1-positive (GLP-1R+) β-tumor cells sorted by FACS from RT2 tumors (Suppl. Figure 9A). To examine whether Ang-1 or Ang-2 were able to activate Tie-2, proteins phosphorylated on tyrosine residues were immunoprecipitated from tumors of RT2, RTRA-1 and RTRA-2 mice and phosphorylated Tie-2 was then detected by immunoblotting with antibodies against Tie-2 (Suppl. Figure 9B). Phosphorylated Tie-2 was found at comparable levels between the three genotype mice. This result was further confirmed by ELISA determining the levels of phospho-Tie-2 (Suppl. Figure 9C) and by immunofluorescence analysis with an antibody specifically recognizing phospho-Tie-2 (Suppl. Figure 10). Together, these analyses revealed that the transgenic expression of Ang-1 and Ang-2 did not significantly change the overall levels of Tie-2 receptor activation.

Previously, it has been reported that Ang-2 and VEGF-A act together to induce angiogenesis. In fact, Ang-2 by itself induces vessel regression in the absence of VEGF-A or upon inhibition of VEGF-A (32). To address whether Ang-2 cooperates with VEGF-A in modulating tumor angiogenesis in RTRA-2 mice we determined VEGF-A mRNA and protein levels in tumors and serum of the various genotype mice (Suppl. Figure 11A, B). Indeed, VEGF-A levels were significantly
higher in RTRA-2 mice and lower in RTRA-1 mice as compared to RT2 control mice. To test the possibility that in RTRA-2 double-transgenic mice, VEGF-A and Ang-2 work synergistically to promote tumor angiogenesis, the small-molecule VEGF receptor inhibitor PTK787/ZK222584 (PTK/ZK; 33) was used to interfere with VEGF receptor function in RTRA-2 mice. PTK/ZK has been previously reported to efficiently repress tumor angiogenesis and tumor growth in the RT2 mouse model (24). Tumor growth and tumor angiogenesis were significantly repressed after treatment of 12 week-old RT2 and RTRA-2 mice with PTK/ZK for 5 days as compared to control-treated mice (Suppl. Figure 12A-C). Notably, the increased endothelial cell numbers in tumors of RTRA-2 mice were substantially reduced upon PTK/ZK treatment to the levels found in RT2 tumors treated with PTK/ZK. This result indicates that the Ang-2-mediated increase in endothelial cell density, as observed in RTRA-2 mice, relies on VEGF-A function. However, the cooperation between Ang-2 and VEGF-A leads to the generation of many non-functional vessels.

Inflammatory cell infiltration in tumors of RTRA-1 and RTRA-2 mice

VEGF-A is known to recruit bone marrow-derived cells to sites of active angiogenesis (34,35). In particular, monocytes/macrophages are well known to contribute to tumor progression and tumor-associated angiogenesis (2,36,37). Immunofluorescence staining revealed that the numbers of tumor-infiltrating F4/80+ macrophages and of 7/4+ neutrophils were significantly reduced in RTRA-1 tumors and significantly increased in RTRA-2 tumors (Figure 6A-D), while the overall numbers of CD45-positive inflammatory cells did not differ between tumors of RT2, RTRA-1 and RTRA-2 mice (Figure 6C, D). However, neither Ang-2 nor Ang-1 were able to affect the infiltration of macrophages or neutrophils into islets of RA-1 and RA-2 mice as compared to C57Bl/6 mice (Suppl. Figure 13).

Ang-1 and Ang-2-mediated tumor lymphangiogenesis
We next determined the lymphatic vessel densities in tumors of RTRA-1 and RTRA-2 double-transgenic mice by LYVE-1 immunofluorescence staining. In agreement with previous reports, tumors of single-transgenic RT2 mice rarely exhibited peri-tumoral lymphatics (38,39). In contrast, tumors of RTRA-1 and of RTRA-2 double-transgenic mice were partially surrounded by lymphatic vessels (Figure 7A, B). The extent of peri-tumoral lymphangiogenesis was quantified by determining the extent by which the tumor perimeters were associated with LYVE-1-positive lymphatic vessels (Figure 7C). The results indicate that both Ang-1 and Ang-2 are able to stimulate peri-tumoral and, more infrequently, intra-tumoral lymphangiogenesis. However, in contrast to the transgenic expression of VEGF-C and VEGF-D in RT2 mice (39,40), the increased lymphangiogenesis in RTRA-1 and in RTRA-2 mice did not result in metastasis to local lymph nodes or to distant organs (Suppl. Figure 7).

Discussion

We have investigated the effects of transgenic expression of human Ang-1 or human Ang-2 in pancreatic β-cells during islet development in RA-1 or RA-2 mice and during β-cell carcinogenesis in double-transgenic RTRA-1 or RTRA-2 mice. Expression of either Ang-1 or Ang-2 has no measurable effect on islet morphology and physiology. In double-transgenic RTRA-1 mice, the transgenic expression of Ang-1 in β-tumor cells exerts only marginal effects on angiogenesis and tumor outgrowth: similar to RT2 controls, the vessels are mature and well perfused, and only tumor cell proliferation is increased as compared to RT2 controls. In RT2, however, most of the blood vessels are already covered by pericytes. Thus, transgenic expression of Ang-1 may only have a redundant function on tumor angiogenesis, and the changes observed in increased pericyte-endothelial cell
association, vessel functionality and tumor growth are subtle and statistically not significant. These results are consistent with previous reports demonstrating that Ang-1 recruits pericytes to blood vessels and leads to an expanded and stabilized, leakage-resistant vasculature (9,41,42).

In contrast, in double-transgenic RTRA-2 mice reduced tumor cell proliferation and tumor growth and increased tumor cell apoptosis is observed. While endothelial cell density is increased in RTRA-2 tumors, vessels are highly disorganized, lack pericyte coverage and are poorly perfused, indicating that endothelial cell density may not give a direct measure of tumor perfusion and tumor growth. These results are in agreement with previous reports demonstrating that Ang-2 expression in xenografted or endogenously growing tumors inversely correlates with pericyte coverage (43,44) or leads to massive tumor vessel regression (45).

In RTRA-1 mice, the numbers of tumor-infiltrating macrophages and neutrophils is found reduced. This could be due to the inhibitory action of Ang-1 on endothelial gap formation and plasma leakage (46). Ang-1 exerts also anti-inflammatory activities, protects against cardiac allograft arteriosclerosis and radiation-induced endothelial-cell damage, and promotes wound healing (5,6). Furthermore, Ang-1 can repress VEGF-induced blood-vessel formation and adhesion-molecule expression.

In contrast, in RTRA-2 mice the numbers of tumor-infiltrating macrophages and neutrophils are significantly increased. Ang-2 is known to promote inflammatory responses by activating the endothelium and inducing vessel permeability (5,6). Tumor-infiltrating inflammatory cells, such as macrophages, neutrophils and mast cells, have been repeatedly shown to play a critical role in the angiogenic switch during tumorigenesis by providing additional angiogenic growth factors, including VEGF-A, and MMPs that activate matrix-associated VEGF-A (2). The elevated levels of VEGF-A (and of other angiogenic factors) lead to overshooting, non-productive
tumor angiogenesis with an increased density of non-functional, immature vessels. VEGF-A is critically involved in the angiogenic switch during tumor progression in RT2 mice, as previously shown by the conditional ablation of VEGF-A expression or adenoviral delivery of soluble VEGF receptors which efficiently blocked tumor angiogenesis and tumor outgrowth (22,26,47). Besides, VEGF induces proteolytic shedding of the extracellular domain of Tie-2 into a 75-kDa soluble fragment (sTie-2) able to bind Ang-1 and to block Tie-2 activation and vessel maturation (48).

Consistent with the notion of increased inflammatory cell infiltration and VEGF-A expression in tumors of RTRA-2 mice, tumor vessel regression and tumor growth arrest is more pronounced when RTRA-2 mice are treated with the VEGF receptor inhibitor PTK/ZK. We conclude that Ang-2 and VEGF act together to induce tumor angiogenesis in RTRA-2 transgenic mice. Hence, Ang-2 exerts a dual function: in conjunction with VEGF-A it exerts a pro-angiogenic activity by promoting vessel sprouting and growth, whereas it destabilizes newly formed blood vessels by preventing mural cell recruitment, vessel maturation and efficient perfusion. As a result of non-functional angiogenesis and impaired vessel perfusion, tumor growth is retarded in RTRA-2 mice. Conversely, it has been reported that repression of Ang-2 activity leads to an inhibition of VEGF-A-mediated angiogenesis and of tumor growth (49).

These findings support a model that a balanced Ang-1:Ang-2 ratio determines the functional status of the vasculature. In RTRA-1 mice, vessel maturation and vessel functionality is maintained by constitutive Ang-1/Tie-2 signaling. The functionality of the vessels ensures appropriate tumor perfusion, high tumor cell proliferation and low apoptosis. In RTRA-2 mice, high levels of Ang-2 destabilize blood vessels and impair their functionality. Yet, on the other hand, Ang-2 primes blood vessels to respond to other cytokines, such as VEGF-A, which induce an inflammatory and angiogenic response, as observed by the increased recruitment of inflammatory cells to the tumor microenvironment.
Our experiments have also revealed a lymphangiogenic activity for both Ang-1 and Ang-2. Peri-insular and peri-tumoral lymphangiogenesis were significantly increased in RA-1 or RA-2 and in RTRA-1 or RTRA-2 transgenic mice. However, the increased lymphangiogenesis in RTRA-1 or RTRA-2 did not provoke the formation of metastasis to regional lymph nodes or distant organs, as has been observed by the transgenic expression of VEGF-C or VEGF-D in Rip1Tag2 mice (39,40). Previously, it has been reported that Ang-1 enhances in vitro colony formation of lymphatic endothelial cells and induces in vivo lymphatic vessel formation in the mouse cornea (30). Conversely, Ang-2-deficient mice exhibit defects in the development and function of the lymphatic vasculature, which can be completely rescued by Ang-1 (31). Thus, Ang-1 and Ang-2 appear to exert similar functions as lymphangiogenic factors during lymphangiogenesis and in lymphatic vessel homeostasis. Whether these functions are exerted via binding exclusively to Tie-2 receptor or to Tie-1/Tie-2 heterodimers or even to other co-receptors warrants further investigations.

Top right: Functional blood vessels were quantified as in (A) in RTRA-2 (N = 3, n = 25) and RT2 (N = 3, n = 18) mice. p < 0.0001***, unpaired Student’s t-test.

Bottom left: Tumoral pericyte density in RTRA-2 (N = 4, n = 42) compared to RT2 (N = 4, n = 30) mice.

Bottom right: Pericyte-coverage of tumoral blood vessels in RTRA-2 (N = 4, n = 42) and RT2 (N = 4, n = 30) mice. p < 0.0001***, unpaired Student’s t-test.

N = number of mice, n = number of microscopic fields (magnification 20x).
Figure 5. Ang-1 promotes and Ang-2 prevents vessel maturation.

(A) Immunofluorescence stainings of intra-tumoral endothelial cells with anti-CD31 antibodies (red) on pancreatic sections from FITC-lectin-perfused (green) RT2, RTRA-1 and RTRA-2 mice. Bars, 100 μm.

(B) Immunofluorescence stainings with antibodies against CD31 (red) and NG2 (green) on 80 μm thick pancreatic sections from RT2, RTRA-1 and RTRA-2 mice. Images were taken with a Leica SP5 laser-scanning confocal microscope. Bars, 20 μm. Boxes indicate regions of higher magnification of single blood vessels (bottom left panels; bars, 4 μm) and their three-dimensional reconstructions using Imaris software (bottom right panels).

Figure 6. Tumor-infiltrating inflammatory cells in RTRA-1 and RTRA-2 mice.

(A and B) Immunofluorescence analysis of tumor-infiltrating macrophages (F4/80+ cells) and neutrophils (7/4+ cells) on pancreatic sections from RT2 and RTRA-1 mice and from RT2 and RTRA-2 mice. Nuclei were visualized by staining with DAPI (blue). Bars, 100 μm.

(C and D) Quantification of tumor-infiltrated CD45+ inflammatory cells, F4/80+ macrophages, and 7/4+ neutrophils in pancreatic tumors from RT2 (N = 3-5, n = 11-57), RTRA-1 (N = 3-5, n = 8-43) and RTRA-2 (N = 3-5, n = 5-44) mice. N = number of mice, n = number of microscopic fields (magnification 20x). p-values, unpaired Student’s t-test.

Figure 7. Ang-1 and Ang-2 induce peri-tumoral lymphangiogenesis.

(A) Lymphatic vessels were visualized by immunofluorescence staining with anti-LYVE-1 antibodies (green) on pancreatic sections from RT2 and RTRA-1. Nuclei were stained with DAPI (blue).
(B) LYVE-1 (green) immunofluorescence staining of pancreatic sections from RT2 and RTRA-2 mice, as in (A).

(C) Quantification of LYVE-1-positive lymphatic vessels on sections of tumors from RT2 (N = 4, n = 33), RTRA-1 (N = 4, n = 31) and RTRA-2 (N = 6, n = 26) mice. Results are presented as the percentages of lymphatic vessel coverage of individual tumors. p < 0.0001, Mann-Whitney test. N = number of analyzed mice, n = number of analyzed individual tumors. Bars, 100 μm.
Figure 3: Fagiani et al.

A

- Total tumor volume (mm$^3$/mouse)
  - RT2
  - RTRA-1

- % of all tumors
  - Islets/hyperplastic
  - Adenoma
  - Carcinoma

B

- Total tumor volume (mm$^3$/mouse)
  - RT2
  - RTRA-2

- % of all tumors
  - Islets/hyperplastic
  - Adenoma
  - Carcinoma

- % pH3+ cells / field
  - RT2
  - RTRA-2

- % caspase-3+ cells / field

- % caspase-3+ cells area (mm$^3$/tumor)
