Abstract

Osteosarcoma is the most common sarcoma in the skeleton, but remains elusive with regard to molecular etiology. MicroRNAs (miRNAs) have demonstrated far-reaching effects on the cellular biology of development as well as oncogenesis. Here we identify an miRNA signature reflecting the pathogenesis of conventional (osteoblastic/fibroblastic) osteosarcoma from surgically procured samples from human patients. The signature includes high expression of \( \text{miR-181a, miR-181b, and miR-181c} \) as well as reduced expression of \( \text{miR-16, miR-29b, and miR-142-5p} \). Osteosarcomas of varied histologic subtype co-localized on unsupervised hierarchical clustering, suggesting that the signature profile relates to oncogenesis itself, rather than simply a differentiation phenotype. We also demonstrated that \( \text{miR-181b and miR-29b} \) exhibit restricted expression to distinct cell populations in the tumor tissue. Further, higher expression of \( \text{miR-27a and miR-181c*} \) in pre-treatment biopsy samples characterized patients who developed clinical metastatic disease. In addition, higher expression of \( \text{miR-451 and miR-15b} \) in pre-treatment samples correlated with subsequent positive response to chemotherapy. \textit{In vitro} and \textit{in vivo} functional validation in osteosarcoma cell lines confirmed the tumor suppressive role of \( \text{miR-16} \) and the pro-metastatic role of \( \text{miR-27a} \). Furthermore, predicted target genes for \( \text{miR-16 and miR-27a} \) were confirmed as down-regulated by real-time PCR. Affymetrix array profiling of cDNAs from osteosarcoma specimens and controls were interrogated according to predicted targets of \( \text{miR-16, miR142-5p, miR-29b, miR-181a/b, and miR-27a} \). This analysis revealed positive and negative correlations highlighting pathways of known importance to osteosarcoma, as well as novel genes. Thus, our findings establish miRNA signatures associated with pathogenesis, metastasis, and responsiveness to treatment in osteosarcoma.
Osteosarcoma MicroRNAs

Introduction

Osteosarcoma (OS) is the most common primary sarcoma of bone and a leading cause of cancer death among adolescents and young adults (1). The cellular events that initiate and propagate osteosarcomagenesis remain poorly understood (2). The vast majority of osteosarcomas (approximately 90%) are termed “conventional” and have osteoblastic and/or fibroblastic histologic patterns with consistently high-grade nuclear morphologies. Two common alternate histologic subtypes, chondroblastic, characterized by cartilaginous tissues in the tumor, and telangiectatic, characterized by abundant vascular and cystic spaces in the tumor, are also often high-grade. When these other subtypes are high-grade, they are treated with conventional osteosarcoma treatment regimens (3).

The genetic and cytogenetic complexity intrinsic to OS make deciphering the origins of its very patterned clinical phenotype especially difficult. Inability to determine which, among the many genetic derangements present in OS, such as aneuploidy, rampant mutations, and manifold copy number variations, are causative of and which are resultant from oncogenic transformation remains a major impediment to progress in understanding its etiology (2). Nonetheless, the consistent clinical pattern of osteosarcomagenesis, characterized by rapid onset of high-grade neoplasms in young people, suggests that some yet undetected, but consistent etiological event or group of events defines the neoplasm.

MicroRNAs (miRNAs) are short non-coding RNAs that post-transcriptionally modify gene expression in eukaryotic cells. Expression of a single miRNA can silence a large number of genes, granting these molecules extensive control over many cellular functions (4). Knowledge of individual miRNAs effecting developmental biology, cellular differentiation programs, and oncogenesis continues to grow (reviewed in (5)). Although specific miRNAs have been functionally evaluated in a few OS cell lines (6-9), and miRNA expression profiled in formalin-fixed paraffin-embedded OS specimens (10), high quality total RNA from primary OS tissues has been collected prospectively in few centers (11). Appreciating the vast effects possible from oncogenic and other miRNAs, we surveyed a well-characterized group of OSs using
array-based technologies. Differential expression profiles were validated with quantitative reverse transcriptase polymerase chain reaction (qRT-PCR), *in situ* hybridization, and functional validation in human OS cell lines both *in vitro* and *in vivo*. Our studies have demonstrated profiles including differential expression of oncogenic and tumor suppressor miRNAs, reflecting OS status.
Osteosarcoma MicroRNAs

Materials & Methods

Patients, sample procurement, and isolation of total RNA

With approval of the institutional review board and in compliance with all legal and ethical considerations for human subject research, patients presenting with suspected sarcomas and scheduled for incisional biopsies provided informed consent to have their tissue banked for RNA extraction. Specimens were obtained during these open surgical biopsies, gently washed with normal saline to remove excess blood, and placed immediately into RNAlater (Ambion, Austin, Texas, USA) by the surgeon. Specimens were kept at 4°C in RNAlater for up to 1 week, then stored at -80°C. When formal pathological interpretation of histology from other portions of the biopsy specimen rendered a diagnosis of osteosarcoma, the RNA-preserving tissue specimens were banked and annotated. In preparation for these specific experiments, total RNA was extracted from banked specimens using the TRIzol reagent and method (Invitrogen, Carlsbad, California, USA). Control samples were derived from to-be-discarded bone fragments obtained from similarly consented patients undergoing debridement surgeries for acute, traumatic injuries to the long-bones.

Microarray profiling of miRNA and mRNA expression

MicroRNA microarray was performed as previously described (12). The integrity of these total RNAs was assessed using an Agilent 2100 bioanalyzer. Five micrograms of total RNA was hybridized on the custom microarray chip (OSUCCC miRNA microchip version 3.0). This array contains approximately 1100 probes (including 345 human and 249 mouse miRNA genes spotted in duplicate). Normalized microarray data were managed and analyzed by BRB-ArrayTools, Version 3.8.1 (13). Genes whose expression differed by at least 1.5 fold from the median, in at least 20% of the arrays were used. A stringent significance threshold was used to limit the number of false positive findings. The result of this approach was determined by two-sample t-test with nominal significance level at 0.01. The FDR is the expected...
**Osteosarcoma MicroRNAs**

Proportion of positive results that are false positives at the various levels of significance and was controlled using the step-up method of Benjamini and Hochberg. In this analysis, at any selected FDR level, the expected proportion of false positives was determined. Class prediction algorithms determined whether microRNA expression patterns could accurately differentiate between OS samples and normal human bone controls. We developed models based on the compound covariate predictor, nearest neighbor classification and support vector machine. The models incorporated genes that were differentially expressed among genes at the significance level (0.05) as assessed by the random variance t-test. We used the prediction test to identify the classifier signature with the lowest misclassification error.

For the mRNA profiling, 14 of the cohort's OS and 4 of the control samples were hybridized with the Affymetrix Human Genome U133 Plus 2.0 Array (Santa Clara, CA). The CEL files were imported and RMA normalized. Genes whose expression differed by at least 1.5 fold from the median in at least 20% of the arrays were used. We performed class comparisons algorithms in BRB-ArrayTools using the paired t-test (p<0.05). The union of the target mRNAs was used as an input to DAVID EASE, using the David Bioinformatics Resources system (http://david.abcc.ncifcrf.gov). We compared the list of terms related to the predicted targeted mRNAs. The terms were evaluated by p-value (P < 0.05) and Benjamini-Hochberg correction for multiple testing controlled the p-values. Target genes selection was performed by Target Scan software. We evaluated Gene Ontology (http://www.geneontology.org/) and PATHWAY (http://www.genome.jp/kegg/) terms.

**RT-PCR validation**

TaqMan miRNA assays were used to detect and quantify mature miRNAs as previously described (14) using ABI Prism 7900HT sequence detection systems (Applied Biosystems). Normalization was
performed with RNA U6. Samples were run in triplicate, including no-template controls. Relative expression was calculated using the comparative Ct method. qRT-PCR to confirm expression levels in cell lines following transfection with lentiviral vectors was performed according to a previously described protocol (15). Primers used are noted Supplemental Table 6.

In situ hybridization

Detection of microRNAs by in situ hybridization was performed as previously published (16, 17). LNA modified probes were 5’ labeled with digoxigenin (Exiqon). After protease digestion to expose the target, 2 pmoles/μL of the probe was hybridized to the tissue section for 15 hours, then subjected to a low stringency wash. The probe-target complex was visualized by alkaline phosphatase activity on the chromogen nitroblue tetrazolium and bromochloroindolyl phosphate (NBT/BCIP) (Roche Diagnostics) after nuclear fast red counterstain. Co-expression analyses was performed with the Nuance system as previously published (17).

Cell lines and cell culture

Cell lines (HOS, KHOS, SaOS2, U2OS, MG-63) were obtained from the American Type Culture Collection (ATCC, Manassas, VA) and hOB from PromoCell (Heidelberg, Germany). Each line was authenticated as to genotype and phenotype by the source company. Cells were utilized at low-passage for experiments, always less than 6 months of passaging post-procurement.

In vitro viral transduction

Lenti-miR-16 was a gift from Dr. Yinon Ben-Neriah (Hebrew University, Jerusalem) and Lenti-miR-27a was described elsewhere (18). HEK293 cells with pCMV-VSVG and pHR82R packaging plasmids were used to produce the lenti-miRs. OS cells at subconfluent density (70%) were incubated with the
Osteosarcoma MicroRNAs

lentivirus for 4-5 hours. Selection with 0.5μg/mL puromycin began the next day. Stable clones were then isolated and verified by qRT-PCR and GFP fluorescence.

Cell proliferation analysis

Cells (1.5 x 10^3) were plated in 96-well plate and analyzed using an XTT (sodium 3(phenylaminocarbonyl)- 3,4- tetrazolium]-bis (4-methoxy- 6-nitro) benzene sulfonic acid hydrate) proliferation assay according to the manufacturer's instructions (Beit Haemek, Israel).

Colony Formation Assay

Cells were plated at a density of 500 cells/well in a 6-well plate in triplicate. After 1-2 weeks the cells were fixed with 70% Ethanol, stained with Giemsa and counted.

Matrigel invasion assay

Blind well chemotaxis chambers with 13-mm-diameter filters were used for this assay. Polyvinylpyrrolidone-free polycarbonate filters, 8-μm pore size (Costar Scientific Co., Cambridge, MA), were coated with basement membrane Matrigel (25 μg per filter). Cells (2 x 10^5) suspended in DMEM containing 0.1% bovine serum albumin, were added to the upper chamber. Conditioned medium of NIH3T3 fibroblasts was placed in the lower chamber. Assays were carried out at 37°C in 5% CO2. Over 90% of the cells attached to the filter after incubation for 7 h. After incubation, the upper surface of the filter was freed of cells with a cotton swab. Cells that passed through the filter to bottom side were fixed with methanol and stained with Giemsa. Each triplicate assay was performed twice. Invasive cells were counted in ten representative light-microscopy fields.

Mouse Experiments
Osteosarcoma MicroRNAs

All animals were housed in the Hebrew University animal facility and the experiments with live animals were approved by our institute animal committee and conducted in accordance with NIH guidelines. HOS cells expressing miR-control, miR16 or miR-27a were injected subcutaneously (SC; 5 × 10^6 cells) or intravenously (IV; 1 × 10^6 cells) into NOD/SCID mice respectively. For SC experiments, tumor volume was evaluated weekly and tumor mass measured at the end of the experiment. For IV experiments, 6-weeks after injecting cells expressing miR-27a-GFP or control-miR-GFP, mice were sacrificed and lungs as well as legs and forearms were examined for micro and macro-metastases, respectively, using a fluorescent stereomicroscope (Olympus).

Immunohistochemistry

Immunohistochemistry was performed on formalin-fixed, paraffin embedded specimens using the following antibodies: polyclonal anti-active caspase-3 (Cell Signaling; dilution 1:100), polyclonal anti-BCL2 (Abcam ab7973-1, dilution 1:100), and polyclonal anti-NFAT5 (Abcam ab110995, dilution 1:100). Detection was performed using ABC kit (BA-1000, VECTOR Laboratories) according to manufacturer's specifications. Slides were reviewed in blinded fashion and ranked according to density of immunostain. Five bone marrow core biopsy controls were used, assessing immunostaining on trabecular bone-rimming osteoblasts.

Results

miRNA expression signature for osteosarcomagenesis

To identify differentially expressed miRNAs common in osteosarcomagenesis, we compared miRNA expression profiles from 18 pretreatment biopsy samples from conventional (osteoblastic/fibroblastic) OSs to control samples from healthy bone tissue (Supplemental Table 1). 34 miRNAs were significantly deregulated (P < 0.01); of those, 11 had higher expression among the conventional OS group and 23
Osteosarcoma MicroRNAs

lower expression (Table 1, Fig 1A). The most up-regulated miRNAs in OS were \textit{miR-181a} and \textit{miR-181b}. \textit{MiR-29b}, \textit{miR-451} and \textit{miR-16} were among the most downregulated. Discrimination by profile between the two groups was strong. The cross-validation receiver operator characteristic (ROC) curve from the Bayesian compound covariate predictor had an area under the curve (AUC) of 0.986. This demonstrates an extremely strong capacity for the relative expression levels of these 34 miRNAs to place a given sample into its correct group, OS or control.

For validation, we performed qRT-PCR for a subset of the samples (Fig 1B). Specifically, qRT-PCR confirmed differential expression for 9 of the 34 significant OS (shown in Fig 1A) miRNAs among a random sampling of 7 specimens from OSs and 4 from controls. In particular, we confirmed the downregulation of \textit{miR-29b}, \textit{miR-16}, \textit{miR-142-5p}, \textit{miR-26b}, \textit{let7g}, \textit{miR-223} and \textit{miR-451} in OS samples as compared to controls. By contrast, \textit{miR-181a} and \textit{miR-181b} showed significant up-regulation in OS cases (Fig 1B). In addition, \textit{miR-29a}, expressed from the same locus as \textit{miR-29b}, was checked by qRT-PCR as a separate validation of the same locus. Other than one sample in each of two of the qRT-PCR experiments, all osteosarcoma samples and control samples had distinct expression ranges, with no overlapping means.

Conventional, chondroblastic, and telangiectatic histologic subtypes of OS have distinct pathologic features. To interrogate the potential contribution of miRNA expression to the development of these different high-grade OS histologic subtypes, miRNA profiles from 18 conventional, 4 telangiectatic, 5 chondroblastic, 1 recurrent chondroblastic, 1 recurrent conventional, and 1 soft-tissue OSs were subjected to unsupervised hierarchical clustering. Conventional, telangiectatic, chondroblastic, and even soft-tissue OSs all clustered together in intermingled fashion (Fig 1C). All 4 telangiectatic OSs clustered to one side of the highest hierarchy division, characterized by elevated expression of \textit{miR-142-5p}, \textit{miR-15a}, \textit{miR-486-5p}, and \textit{miR-488}. Small sample size makes statistical resolution of this finding unfeasible.

Both conventional and chondroblastic OSs clustered with those 4 telangiectatic OSs. The overall co-
Osteosarcoma MicroRNAs

clustering of different subtypes suggests that with regard to miRNA expression, these tumors share
more in common than not, which suggests that the miRNA expression represents more a shared
oncogenic program than a differentiation profile alone, as these tumors are distinctly dissimilar in cell
differentiation state. MiRNA profiling therefore may not be helpful in defining histologically-based OS
subtype classifications.

To validate against an alternate data set, the publicly available S-MED database (19) was queried for the
34 miRNAs highlighted by our OS signature. The 15 osteosarcoma samples (not subtyped) and 6 control
bone samples recorded in the S-MED database had raw expression data for 26 of these miRNAs.

Expression of 17 corroborated the differential expression in our samples (8 were significant with
Student’s t-test p-values ranging from 0.006 to 5x10^{-8}.). These statistically significant and concordant
expression data included higher expression of miR-181c and miR-190 in S-MED OS specimens and lower
expression of miR-16, miR-126*, miR-150, miR-195, miR-657, and miR-340. While the S-MED database
includes fewer OS specimens than our primary data and lacks any clinical or pathologic annotation, it
provides validation of the most important members of our osteosarcoma miRNA signature profile from
an alternate sample source and profiling platform.

**miR-181b is inversely correlated with miR-29b in OS**

To confirm deregulation of miRNA expression within tumor cells specifically, *in situ* hybridization of
probes anti-sense to the differentially expressed miR-181b and 29b was performed using formalin-fixed
paraffin-embedded tissue sections processed from 9 of the same pre-treatment biopsy specimens from
which fresh tissue for total RNA isolation had been initially banked. As shown in Fig 2, *in situ*
hybridization with locked nucleic acid (LNA)-modified anti–miR-181b (B) or anti-miR-29b (C) probes
showed results consistent with qRT-PCR (D). No signal was detected with scrambled oligo,
demonstrating probe specificity (data not shown). Some tissues showed positive hybridization for the
Osteosarcoma MicroRNAs

down-regulated miRNA-29b (Fig 2D). While down-regulation is not tantamount to absence, this nonetheless prompted further investigation. Using double-labeling for miR-29b and miR-181b, it was confirmed that expression did not co-localize to the same cells (Fig 2E, F), suggesting that the pro-osteoblast-differentiation miR-29b was specifically absent in cells with the most robust oncogenic program of miR-181b expression. Additional in situ hybridization validation was performed using a bone cancer tissue microarray (US Biomax, Inc. Rockville, Maryland, USA) that included 8 core tissue sections from 4 OSs. Four of the samples from 2 of the OS specimens demonstrated strong staining for miR-181b and minimal staining for miR-29b.

miRNA expression signatures for osteosarcoma metastasis and chemotherapeutic response

Ten OS patients either presented with or later developed clinically apparent metastatic disease. Their biologically aggressive tumors clustered together on unsupervised hierarchical clustering, loosely separate from the comparison 19 localized OSs (Fig 3A). Differentially expressed miRNAs included 1.75- and 4.53-fold increased expression of miR-181c* and miR-27a, respectively, in metastatic OSs. The class prediction analysis using these two miRNAs yielded a relatively strong ROC curve with an AUC of 0.805, indicating that the expression level of these two miRNAs alone discriminated between tumors that would and would not develop clinical metastases.

As OS patients typically receive chemotherapy after biopsy, but before resection, the percent necrosis or treatment effect noted by the pathologist in the resection specimen has been found to be a powerful prognostic tool (20). All OS patients with pre-treatment sample miRNA profiles available and who received neoadjuvant chemotherapy followed by resection and histopathologic grading of necrosis (n=27, Supplemental Table 1), were analyzed for a correlation between differentially expressed pre-treatment miRNAs and the percent necrosis following chemotherapy. Spearman correlation, which measures the correlation of rank-ordering between two values, identified expression of 8 miRNAs
Osteosarcoma MicroRNAs

positively correlated with percent necrosis at <0.01 stringency and 1 negatively correlated (Supplemental Table 2A; Fig 3B shows unsupervised clustering by Spearman-identified miRNAs).

Pearson correlation, which identifies linear relationships rather than rankings, identified 7 miRNAs positively correlated with necrosis at <0.01 stringency (Supplemental Table 2B; Fig 3C shows unsupervised clustering by Pearson-identified miRNAs). *MiR-451* and *miR-15b*, with the two highest Spearman correlation coefficients of 0.64 and 0.619, respectively, were also highlighted by the Pearson correlation list, having correlation coefficients of 0.533 and 0.539, respectively. Thus, increased expression of *miR-15b* (from the *miR-15/16* family) and *miR-451* in pre-treatment samples was the most stringent predictor of good response to chemotherapy. RT-PCR validated expression levels of *miR-451* and *miR-15b* in a subset of chemosensitive and chemoresistant OS samples (Supplemental Figure 1).

**Functional validation of *miR-16* as tumor suppressive in OS cells.**

To determine the functional relevance of miRNA deregulation in OS, we studied the effect of *miR-16* and *miR-27a* manipulation on OS cells. We first checked the endogenous *miR-16* and *miR-27a* levels by qRT-PCR in one human osteoblast and 6 human osteosarcoma cell lines. Three OS cell lines (HOS, KHOS and U2OS) exhibited significantly low levels of *miR-16* as compared to hOB (Supplementary Fig S2). Similarly, *miR-27a* expression levels were lower in these cells while the MG-63 cells, capable of metastasis and the highly metastatic LM-7 cells displayed higher levels (Supplementary Fig S2).

Next, we set to determine whether re-introduction of these miRs affected the tumorigenic traits of OS cells (Supplementary Fig S3, 4). Using XTT test, we observed significant growth inhibition in U2OS and hOB cells (Supplementary Fig S5). In contrast, we did not detect this effect in HOS, KHOS and SaOS2 cells (Fig 4A, Supplementary Fig S5). Nevertheless, overexpression of *miR-16* in OS cells displaying low levels of endogenous *miR-16* was associated with significant reduction in colony formation ability (Fig 4B and
Supplementary Fig S5). Moreover, HOS expressing miR-16 displayed increased apoptosis in the presence of doxorubicin (Figure 4C).

We next evaluated the tumor suppressor function of miR-16 in vivo. HOS cells overexpressing control miR or miR-16 were xenografted into the flanks of NOD/SCID mice and monitored for tumor formation. We found that overexpressing miR-16 produced tumors of smaller volume and smaller final mass (Figure 4D-F). Furthermore, miR-16 overexpressing HOS xenografts exhibited increased activated caspase-3 staining (Figure 4G), an indicator of enhanced apoptosis in the absence of cytotoxic treatment.

**Functional validation of miR-27a as pro-metastatic in OS cells.**

In order to interrogate the impact of miR-27a overexpression on the metastatic potential of OS cells, we infected HOS cells with a lentiviral vector that expresses either miR-27a or control miR along with a green fluorescent protein (GFP) reporter. *In vitro*, a wound healing assay demonstrated increased migration with overexpression of miR-27a versus control miR (Figure 4H). Similarly, matrigel invasion assay showed that miR-27a increased invasiveness (Figure 4I). miR-27a expressing cells were next injected intravenously into NOD/SCID mice to evaluate the metastatic potential of these cells. Six weeks later, the animals were scarified and dissected to look for both microscopic and macroscopic metastases. We found that overexpression of miR-27a is associated with increased ability to form metastatic foci compared to control miR. The number and size of pulmonary metastases was significantly increased as well as the presence of macroscopic metastatic disease in the bones of the legs and forearms (Figure 4J-N). Additional functional validation in other cell lines confirmed pro-migration and invasion effects of miR-27a (Supplementary Fig S5).

**Predicted targets of differentially expressed miRNAs reflected in osteosarcoma**
Osteosarcoma MicroRNAs

MiRNAs are known to have downregulatory effects at the level of transcript longevity and translational control. Expression levels of TargetScan-predicted target genes of miR-16 were found to be reduced in OS and osteoblast cell lines following overexpression of miR-16 (Fig 5A). Similarly, expression levels of predicted target genes of miR-27a were found to be reduced in OS cell lines following overexpression of miR-27a (Fig 5B).

We expanded the analysis of expression of target genes by profiling gene expression by Affymetrix array in 14 of the OS samples in our cohort and 4 of the normal bone control samples. Our data revealed differential changes in a significant number of genes (data not shown). The miRNA and mRNA expression profiles were then integrated to identify functional relationships that may contribute to OS. Instead of correlating gene expression with all miRNAs, we focused on miRNAs whose differential expression was most significant in OS; miR-16, miR-142-5p, miR-29b as down-regulated miRNAs in OS and miR-181 and miR-27a as up-regulated miRNAs in OS. Positive and negative correlations were found. However, we focused on the differentially expressed genes that followed the directional change predicted by the miRNA; increased expression in OS for genes targeted by miR-16, miR-142-5p, and miR-29b, and decreased expression of genes targeted by miR-181 and miR-27a (Supplementary Tables 3A-3B). We found that several known OS genes are indeed targeted by these different miRNA classes.

Gene ontologies and Kegg pathways analyses of these predicted target genes highlighted significant changes in transcriptional regulation, cell cycle control, and known cancer signaling pathways (Table 2 and Supplementary Tables 4 and 5).

To further investigate one miRNA as an example, miR-15b from miR-15/16 family was selected due to the fact that it showed differential expression within the cohort of osteosarcomas and predicted chemosensitivity. The expression level of miR-15b from each specimen was plotted against the Affymetrix mRNA level in the same sample for six of the prominent differentially expressed genes that are predicted targets and responsive in cell line experiments (Fig 5C). A linear regression trendline for
Osteosarcoma MicroRNAs

each series showed the predicted direction of correlation with increasing level of \textit{miR-15b} linked to decreasing levels of each gene's mRNA. Because miRNAs can have more profound effects on translation than transcription, we performed immunohistochemistry in tissue sections from a subset of the OS samples. We selected two genes, one a well-known gene in osteosarcoma, \textit{BCL2}, the other a gene not previously associated with osteosarcoma, but also a target of the \textit{miR-15/16} family, \textit{NFAT5}. For both, immunohistochemistry confirmed increased protein presence in the cohort OSs than in the osteoblasts of bone marrow controls (Supplementary Fig S6). The BCL2-immunohistochemically stained sections were blindly ranked from least to most positive for staining. This ranking was then plotted against the expression level of \textit{miR-15b} (Fig 5D) and against the expected clinical parameter of percent necrosis as measured from later resection surgery to quantify chemoresponsiveness (Fig 5E). Linear regressions strongly followed the expected correlation in each. While these correlations only consider one example, they suggest that the differentially expressed miRNAs play a direct role in controlling transcript levels and translational success of predicted target genes in OS.

Discussion

We report unique OS signatures of miRNA expression related to the OS character and pathogenesis, to clinical metastasis, and to chemotherapy response. The deregulation of \textit{miR-181b} specifically in the malignant cells in OS tissues by \textit{in situ} hybridization provides a potential OS marker. Further, \textit{miR-181b} and \textit{miR-29b} expression inversely correlate in subpopulations of cells in the tumors. Significantly, our \textit{in vitro} and \textit{in vivo} functional experiments validate \textit{miR-16} as a tumor suppressor and \textit{miR-27a} as pro-metastatic in OS and osteoblast cell lines. These data suggest potential targets for future therapeutic
Osteosarcoma MicroRNAs

strategies. Further, our study indicates that by correlating genome wide gene and miRNA expression profiles, putative functional miRNA-mRNA interactions could be identified in OS.

The conventional OS miRNA expression signature we report showed strong statistical significance even in a relatively small sample size. This suggests profile consistency across the samples. Given the genetic and cytogenetic complexity inherent to OS (2), this consistency raises the possibility that miRNAs play a central role in osteosarcomagenesis. That the miRNA profile differed little even among histologically disparate samples from chondroblastic and telangiectatic OSs further suggests a role for these miRNAs in development of OS generally. Validation against another patient group confirmed the differential expression of the critical members of this (19). A final validation of our signature derives from our observation that some of the prominent signature miRNAs are also highlighted by OS metastasis and chemotherapy responsiveness signatures (Supplementary Fig S7).

As we qualitatively evaluate these signature OS miRNAs, downregulated miRNAs are most striking. MiR-29b figured prominently in this list. We also demonstrated its localization to a distinct cell subpopulation within the tumors. This fits the powerful role of miR-29b as a pro-differentiation miRNA in normal osteoblasts (21). Other signature downregulated miRNAs have known pro-differentiation roles in other tissues, miR-223 in myeloid (22) and miR-451 in erythroid differentiation (23). MiR-29b is also known as a tumor suppressor miRNA (24). The tumor suppressor category also encompasses other prominently downregulated members of the signature profile, including miR-142-5p (25), miR-340 (26), breast cancer metastasis suppressing miR-335 (27), BCL-2 targeting miR-16/16-2* (Reviewed in (28)), miR-126/126* (Reviewed in (29)), and miR-195 (30), a miR-15/16-related miRNA. Together with our in vitro functional validation for miR-16, these findings highlight critical tumor-suppressor functions of the miR-15/16 family in OS.

Most upregulated miRNAs in the OS signature are known oncomiRs, such as miR-190 (31), miR-10b ((32) and references therein), miR-7 ((33) and references therein), miR-214 ((34) and references therein), and
Osteosarcoma MicroRNAs

miR-210 (35). Although miR-574-3p is not well-characterized in the literature, it is predicted to target disabled homolog 2 interacting protein (DAB2IP), which is silenced in a number of cancers (36-38), retinoid X receptor alpha (RXRA), which is associated with vitamin D metabolism and polymorphism-based cancer risk (39), and FOS like antigen 2 (Fosl2/Fra2), which is a pro-differentiation gene in osteoblasts (40). Most prominently, three of the four miRNAs from the miR-181 group were highly upregulated in OS samples. MiR-181 has been associated with stemness and poor prognosis in other cancers (41) and references therein). Further, miR-181 activates Wnt signaling (42), important in OS pathogenesis (43). Together with our in situ hybridization confirmation that miR-181 identifies a subgroup of cells within OS tissues that lack miR-29b-driven differentiation, these data highlight miR-181 as a critical OS oncomiR.

Increased expression of miR-181c* and miR-27a at pre-treatment biopsy was found to be prognostic of metastatic disease. This punctuates the importance of the miR-181 family to OS. miR27a is a known oncomiR, associated with metastasis in gastric cancer (44) and poor prognosis in ovarian carcinoma (45).

Our in vitro and in vivo experiments confirmed that miR-27a overexpression enhances migration, invasion, and proliferation in metastatic sites. These findings correlate with the recently described inhibition of osteoblast differentiation by miR-27a (18). Targeted therapies against miR-27a are emerging (46, 47).

Expression levels of miR-451 and miR-15b in pre-treatment specimens both correlated positively with percent necrosis following neoadjuvant chemotherapy. Reduced expression of miR-451 was also prominent in the general OS signature. While miR-15b itself was not highlighted in the general OS signature, miR-16, miR16-2*, and miR-195, all from the same miR-15/16 family, were. Apparently, reduced expression of these miRNAs characterizes OS generally, but among OSs, further reduced expression correlates with resistance to chemotherapy. MiR-15b and other family members target Bcl-2, which could explain their downregulation in chemo-resistant tumors (48). We confirmed by
immunohistochemistry the increased presence of BCL-2 in the OS histologic specimens compared to controls. Further, increased apoptosis was identified both in untreated xenografts and doxorubicin-treated cultures of OS cells driven to overexpress miR-16. Our findings did not corroborate any of the specific miRNAs reported to predict chemotherapeutic response in a series of formalin-fixed paraffin-embedded OS specimens (10). This other study differed in source and method of RNA isolation. It also focused on ifosfamide, an infrequent neoadjuvant chemotherapy for OS in the United States and received by only one of our patients. Further, our findings did not highlight any of the previously investigated individual miRNAs noted to have roles in osteosarcoma cell lines(6-9).

The profound effects of miR-16, miR-142-5p, miR-29b, miR-181, and miR-27a on the microarray-defined expression of their predicted target genes, with statistically significant differences in the predicted direction, suggest that these miRNAs play central roles in defining the expression identity of OS. Our study reveals many potential functional miRNA-mRNA relationships that will need to be further explored mechanistically for their involvement in OS pathogenesis. Gain and loss of function studies are needed to investigate further the role of these miRNAs that have correlated with transcriptional regulation, cell cycle control, and known cancer signaling pathways. Finally, the discovery of previously unidentified functional relationships may lead to the development of novel therapeutic approaches. Further investigation into the potentially more poignant effects on translation of their targets may yield additional insights into this newly recognized method of an OS cell defining itself.

Making clear sense of how the genetic chaos that defines OS derives such a patterned clinical disease remains a distant goal, but these data strongly recommend the pursuit of osteosarcomiRs and silenced OS tumor suppressor miRNAs as critically associated with development of OS. The statistical strength of the OS signature we report, the consistency across multiple histologic subtypes, and especially the overlap of the general OS signature with signatures predictive of metastasis and predictive of response.
**Osteosarcoma MicroRNAs**

to chemotherapy all highlight the central role of these dysregulated miRNAs in osteosarcomagenesis. Our validation studies for key signature OS miRNAs and integration of miRNA expression with mRNA expression, together with existing literature provide models for future study.

### Figure Legends

**Figure 1.** An miRNA expression signature for osteosarcoma. (A) Unsupervised clustering of miRNA expression profiling from 18 pre-treatment tumor total RNA obtained from conventional osteosarcomas in comparison to 12 normal bone tissues. (B) Quantitative (q)RT-PCR confirmed differential expression for a subset of control and osteosarcoma samples and a subset of highlighted miRNAs. (C) Unsupervised clustering of miRNA expression profiles from 30 pre-treatment tumor total RNA samples of varied histologic subtypes, demonstrating co-clustering.

**Figure 2.** Validation by *in situ* hybridization. Formalin-fixed, paraffin-embedded tissues from the same biopsies that rendered the total RNA samples were sectioned and stained with hematoxylin and eosin (A), or probed with anti-sense oligonucleotides against *miR-181b* (B) or *miR-29b* (C). The percent cells hybridizing to the tested probes were generated from counting 10 high powered fields (D). Samples with both *miR-181* and *miR-29b* hybridization were subjected to cohybridization with differentially labeled detection systems, demonstrating little to no overlap in positive cells (*miR-29b* stained red in E and fluorescent green in F, *miR-181* stained blue in E and fluorescent blue in F).

**Figure 3.** miRNA expression profiling identifies behavioral subgroups of osteosarcoma. (A) Unsupervised clustering according to expression of miRNAs differentially expressed in pre-treatment samples from osteosarcomas that present or develop clinical metastasis or remain clinical localized through treatment and follow-up. (B) Unsupervised hierarchical clustering of osteosarcomas according their pre-treatment expression of miRNAs that correlate by Spearman correlation coefficient with percent necrosis following neoadjuvant chemotherapy. (C) Unsupervised hierarchical clustering of osteosarcomas according their pre-treatment expression of miRNAs that correlate by Pearson correlation coefficient with percent necrosis following neoadjuvant chemotherapy.
