Intestinal GUCY2C Prevents TGF-β Secretion Coordinating Desmoplasia and Hyperproliferation in Colorectal Cancer

Ahmara V. Gibbons, Jieru E. Lin, Gilbert W. Kim, Glen P. Marszalowicz, Peng Li, Brian A. Stoecker, Erik S. Blomain, Satish Rattan, Adam E. Snook, Stephanie Schulz, and Scott A. Waldman

Abstract

Tumorigenesis is a multistep process that reflects intimate reciprocal interactions between epithelia and underlying stroma. However, tumor-initiating mechanisms coordinating transformation of both epithelial and stromal components are not defined. In humans and mice, initiation of colorectal cancer is universally associated with loss of guanylin and uroguanylin, the endogenous ligands for the tumor suppressor guanylyl cyclase C (GUCY2C), disrupting a network of homeostatic mechanisms along the crypt-surface axis. Here, we reveal that silencing GUCY2C in human colon cancer cells increases Akt-dependent TGF-β secretion, activating fibroblasts through TGF-β type I receptors and Smad3 phosphorylation. In turn, activating TGF-β signaling induces fibroblasts to secrete hepatocyte growth factor (HGF), reciprocally driving colon cancer cell proliferation through cMET-dependent signaling. Elimination of GUCY2C signaling in mice (Gucy2c−/−) produces intestinal desmoplasia, with increased reactive myofibroblasts, which is suppressed by anti-TGF-β antibodies or genetic silencing of Akt. Thus, GUCY2C coordinates intestinal epithelial–mesenchymal homeostasis through reciprocal paracrine circuits mediated by TGF-β and HGF. In that context, GUCY2C signaling constitutes a direct link between the initiation of colorectal cancer and the induction of its associated desmoplastic stromal niche. The recent regulatory approval of oral GUCY2C ligands to treat chronic gastrointestinal disorders underscores the potential therapeutic opportunity for oral GUCY2C hormone replacement to prevent remodeling of the microenvironment essential for colorectal tumorigenesis. Introduction

Tumorigenesis reflects an intimate collaboration between cancer cells and the supporting microenvironmental stroma (1–3). Genetic changes underlying malignant transformation corrupt circuits regulating epithelial–mesenchymal cross-talk that are essential for normal tissue organization, homeostasis, and regeneration (4). This reprogramming drives the coevolution of epithelial cells and their supporting microenvironment, producing reactive stroma that allows tumor cells to acquire the hallmarks of cancer (2, 5, 6).

The dynamic changes in cancer-associated stroma resemble the desmoplastic reaction of wound healing, characterized by extracellular mesenchymal remodeling with increased matrix deposition and matrix metalloproteinase (MMP) activity (4).

Tumor-associated desmoplasia is supported primarily by the transformation of quiescent host fibroblasts into myofibroblasts (1, 2, 7, 8). Although normal stroma contains few fibroblasts, there is an increase in activated myofibroblasts within the reactive stroma surrounding tumors (8). Induction of the myofibroblastic phenotype in quiescent fibroblasts is supported by the secretion of TGF-β by cancer cells (1, 3, 9). Reciprocally, myofibroblasts play an essential role in solid tumors by producing paracrine and juxtacrine factors, including HGF, that drive normal epithelial cells toward acquiring the malignant phenotype (1, 5, 6, 10–14).

Paracrine cross-talk between epithelia and mesenchyme is essential to cancer progression and metastasis (15), but the precise signaling mechanisms linking tumor-initiating events to desmoplastic induction remain incompletely defined. For example the cell type coordinating epithelial and mesenchymal reprogramming at the initiation of transformation remains unknown (2, 8, 16). Thus, dissecting the individual stromal and epithelial contributions would define the paracrine signaling loops initiating and supporting carcinogenesis and provide new targets for tumor prevention and therapy.

Guanylyl cyclase C (GUCY2C) is the intestinal isofrom of the family of guanylyl cyclase transmembrane receptor enzymes that signal by producing cyclic guanosine 3′,5′—monophosphate (cGMP; ref. 17). GUCY2C was first identified as the intestinal epithelial receptor regulating fluid and electrolyte transport in the secretory diarrhea induced by bacterial enterotoxins (ST; ref. 17). Discovery of the endogenous...
paracrine hormones uroguanylin, in the small intestine, and guanylin, in the colorectum (18), revealed a role for GUCY2C in epithelial cell dynamics and the homeostatic balance of proliferation, metabolism, and differentiation that organizes the crypt-surface axis in the intestine (19–23).

Notably, guanylin and uroguanylin are the most commonly lost gene products in intestinal tumorigenesis in animals and humans, and their expression is universally silenced at the earliest stages of transformation (24–27). Furthermore, eliminating GUCY2C amplifies the tumorigenesis induced by carcinogens or gene mutations in mice (20, 21). Indeed, silencing GUCY2C activates the AKT-mTOR signaling axis, which imparts cell-autonomous characteristics of transformation to intestinal epithelial cells, encompassing accelerated proliferation, reprogramming of metabolism from oxidative phosphorylation to aerobic glycolysis, and impaired DNA damage repair (19–23). Moreover, oral administration of GUCY2C hormone attenuates the colorectal tumorigenesis induced by adenomatous polyposis coli (APC) mutations in mice (25).

GUCY2C has emerged as a novel intestinal tumor suppressor. In the heart, the natriuretic peptide receptor guanylyl cyclase A isoform (NPR1) is expressed in cardiomyocytes and establishes a homeostatic balance with the mesenchymal components (28, 29). Silencing cardiomyocyte NPR1 and cGMP signaling produces cardiac hypertrophy and elevated interstitial fibrosis (28, 29). In fact, increases in growth and fibrosis are disproportionate to and perhaps even independent of increases in blood pressure or volume, suggesting that NPR1 acts through local, paracrine pathways to suppress hypertrophy and desmoplasia (28, 29). The paracrine mechanisms mediating this cardiomyocyte–mesenchymal cross-talk remain incompletely characterized. However, based on this role of NPR1 and cGMP signaling in the heart, the present study explored whether the tumor suppressor GUCY2C and cGMP had homologous functions in the intestine, namely the maintenance of epithelial–mesenchymal homeostasis whose corruption contributes to tumor-associated desmoplasia.

Materials and Methods

Animal models

Gucy2c−/− wild-type littermate mice on the C57BL/6 background (generation 14) were bred, maintained, genotyped, and functionally characterized in accordance with the Thomas Jefferson University Animal Care and Use guidelines (19–21). Akt1+/−/Gucy2c−/+ and Akt1+/−/Gucy2c−/− were bred from Akt1+/−/Gucy2c−/+ genotyped, and functionally characterized as described previously in accordance with the Thomas Jefferson University Animal Care and Use guidelines (21). Where indicated, animals received an intraperitoneal dose (0.5 mg/kg) of immunoglobulin G (IgG; Innovative Research) or TGF-β1 (R&D Systems) at a concentration (10 ng/mL) corresponding to that produced by T84 cells, quantitated by ELISA (R&D Systems). In experiments using TGF-β1 receptor inhibitors, colon cancer cells were treated with PBS or 1 μmol/L ST for 48 hours before the conditioned media was transferred to CCD-18Co cells pretreated for 0.5 hours with the TGF-β1 type I receptor inhibitor SB-505124 (50 nmol/L; Sigma-Aldrich). SB-505124 treatment continued in the conditioned media for the indicated times. In experiments using siRNA, colon cancer cells were transfected with TGF-β1–targeted or control siRNA (100 nmol/L; ABI) by Amaxa Electroporation (Lonza) 48 hours before use in conditioned media transfer experiments, to permit adequate time for suppression of TGF-β1 expression.

Akt activation and inhibition in cancer cells

T84 were infected with adenovirus-expressing siAKT1 and GFP control for inhibition experiments, or adenovirus-expressing wtAKT1 and myrAKT1 for activation experiments, at 50% confluence using multiplicity of infections (MOI) of 100 at 48 hours before GUCY2C activation during starvation (21). Then, cells were washed and incubated in complete media with 1 μmol/L ST or PBS (control) for 48 hours. The conditioned media were transferred to fibroblasts after dilution as described earlier.

HGF production by fibroblasts and cMET activation

Media conditioned by T84 cells with and without activation of GUCY2C signaling by 1 μmol/L ST or PBS (control) for 48 hours in DMEM–F12 and Dulbecco’s Modified Eagle Medium (Cellgro) media supplemented with 10% FBS (21). CCD-18Co normal human intestinal fibroblasts were cultured and maintained in Eagle Minimum Essential Medium (ATCC). In studies of fibroblast induction, T84 or Caco2 cells were cultured in Minimum Essential Medium (MEM; Cellgro) without FBS for 48 hours. Then, completed growth media were conditioned by cancer cells for another 48 hours, including either the GUCY2C ligand, ST (1 μmol/L), or vehicle, PBS (21, 22). Conditioned media were centrifuged at maximum speed for 5 minutes to precipitate cancer cells and then diluted with 2 parts of Opti-MEM GlutaMAX (Invitrogen) to obtain a 1:3 dilution before applying to fibroblasts for 24 hours. Notably, T84 and Caco2 cells express GUCY2C, which mediates canonical downstream cGMP signaling upon ligand binding (19–21). In contrast, CCD-18Co do not express GUCY2C and are unresponsive to ligands targeting that receptor.

Antibody treatment, TGF-β1 receptor inhibitors, and siRNA transfection

In experiments exploring the role of cancer cell TGF-β1 in fibroblast activation, T84 or Caco2 cell–conditioned media were treated with a neutralizing antibody to TGF-β1 (30 ng/μL) or control IgG (30 ng/μL). In some experiments, TGF-β1 produced by colon cancer cells was depleted from conditioned media with neutralizing antibody to TGF-β1 (30 ng/μL) followed by immunoprecipitation with Dynabeads Protein G (Invitrogen). Cancer cell–derived TGF-β1 removed by immunoprecipitation was replaced with recombinant purified TGF-β1 (rTGF-β1; R&D Systems) at a concentration (10 ng/mL) corresponding to that produced by T84 cells, quantitated by ELISA (R&D Systems). In experiments using TGF-β1 receptor inhibitors, colon cancer cells were treated with PBS or 1 μmol/L ST for 48 hours before the conditioned media was transferred to CCD-18Co cells pretreated for 0.5 hours with the TGF-β1 type I receptor inhibitor SB-505124 (50 nmol/L; Sigma-Aldrich). SB-505124 treatment continued in the conditioned media for the indicated times. In studies using siRNA, colon cancer cells were transfected with TGF-β1–targeted or control siRNA (100 nmol/L; ABI) by Amaxa Electroporation (Lonza) 48 hours before use in conditioned media transfer experiments, to permit adequate time for suppression of TGF-β1 expression.

Cell culture and fibroblast activation

T84 and Caco2 human colon cancer cells were maintained and cultured in DMEM–F12 and Dulbecco’s Modified Eagle Medium (Cellgro) media supplemented with 10% FBS (21). CCD-18Co normal human intestinal fibroblasts were cultured and maintained in Eagle Minimum Essential Medium (ATCC). In studies of fibroblast induction, T84 or Caco2 cells were cultured in Minimum Essential Medium (MEM; Cellgro) without FBS for 48 hours. Then, completed growth media were conditioned by cancer cells for another 48 hours, including either the GUCY2C ligand, ST (1 μmol/L), or vehicle, PBS (21, 22). Conditioned media were centrifuged at maximum speed for 5 minutes to precipitate cancer cells and then diluted with 2 parts of Opti-MEM GlutaMAX (Invitrogen) to obtain a 1:3 dilution before applying to fibroblasts for 24 hours. Notably, T84 and Caco2 cells express GUCY2C, which mediates canonical downstream cGMP signaling upon ligand binding (19–21). In contrast, CCD-18Co do not express GUCY2C and are unresponsive to ligands targeting that receptor.
hours were used to induce fibroblast activation of CCD-18Co cells following incubation for 24 hours. Then, fibroblast-conditioned media were transferred to HCT116 human colon cancer cells, which do not express GUCY2C and possess inactivating mutations in the TGF-β receptor (21, 31), and proliferation was quantified using 3H-thymidine (21–23). HCT116 cells are particularly useful for quantifying the effects of fibroblast-derived HGF on colon cancer cell proliferation in the absence of confounding by GUCY2C or TGF-β ligands. In some experiments, media sequentially conditioned by human cancer cells and then by fibroblasts were treated with a neutralizing antibody to HGF or control IgG (20 μg/mL; R&D Systems). Where indicated, HGF produced by fibroblasts was depleted from conditioned media with neutralizing antibody to HGF (20 μg/mL) followed by immunoprecipitation with Dynabeads Protein G (Invitrogen). Fibroblast-derived HGF depleted by immunoprecipitation was replaced with recombinant purified HGF (rHGF; 2.5 ng/mL; R&D Systems). In some experiments, HCT116 cells were pretreated with cMet Kinase Inhibitor III (500 nmol/L; EMD Millipore), an inhibitor of cMET, the canonical receptor for HGF (32), for 5 minutes before incubations with conditioned media.

**Immunoblot analyses and immunofluorescence**

Protein was extracted from cells and tissues in M-PER reagent supplemented with protease and phosphatase inhibitors (Thermo Scientific) and quantified by immunoblot analysis using antibodies to procollagen I (Sigma-Aldrich), α-SMA and MMP-9 (Biomol), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and prolyl hydroxylase-β (Abcam). Other antibodies were from Cell Signaling Technology. Anti-α-smooth muscle actin (α-SMA; Sigma-Aldrich), anti-collagen I, and anti-β-catenin (Santa Cruz Biotechnology) antibodies were used to stain fibroblasts and epithelial cells, respectively (1, 33). Expression levels were quantified by estimating the integrated density of the protein of interest and normalizing to the integrated density of the nucleus (4, δ-amidino-2-phenylindole, DAPI). Stained tissues were quantified in 5 to 10 crypt units in 5 to 10 sections in each mouse.

**Masson trichrome stain**

Tissue collected from mice were deparaffinized and stained with Weigert iron hematoxylin solution and Biebrich scarlet-acid fuchsin, placed in phosphomolybdic/polyphosphotungstic acid solution, and counterstained with Aniline blue (Dako) or Masson Trichrome Stain Kit (Sigma-Aldrich). The bottom of crypts was identified by the presence of Paneth cells. In Figure 1, the interstitial thickness was calculated as area of the blue stain divided by the length of the underlying muscle layer, quantified in Image J. In Figure 6, the interstitial thickness displays the shortest distance between the bottom of the crypt and the muscle layer. In both cases, pixels were converted back to metric dimensions. Quantification represents data from 5 to 10 crypt units in 5 to 10 sections per mouse.

**Hydroxyproline assay**

Tissue was freeze-dried, homogenized, and hydrolyzed in 0.5 mL of 5 mol/L HCl for 16 hours at 116°C. Samples were dried, dissolved in distilled water, and hydroxyproline quantified using a colorimetric demethylmethylene blue assay (Sigma-Aldrich; ref. 34).

**Collagen contractility assay**

CCD-18Co cells and Type I Collagen (Sigma-Aldrich) dissolved in acetic acid (0.1%) was used to access functional differences in contractility between quiescent fibroblasts and fibroblasts (35). After solutions were neutralized with NaOH (1 mol/L), cells were suspended in the collagen, plated, and cancer cell–conditioned media was added (35).

**Quantitative reverse transcriptase PCR**

Total RNA was subjected to one-step reverse transcriptase (RT)-PCR using TaqMan EZ RT-PCR Core Reagents and specific primer/probes for TaqMan Gene Expression Assays in an ABI 7000 (Applied Biosystems; ref. 36). Relative expression was calculated using the 2−ΔΔCt method with GAPDH or β-actin as reference (36).

**Electron microscopy**

Intestinal samples were collected, processed, fixed, and embedded as previously described (21). Ninety-nanometer sections were imaged with a JEOL-1010 electron microscope using 80 kV of acceleration.

**Statistical analyses**

Statistical significance was determined by unpaired two-tailed Student t test. Unless otherwise indicated, results represent means ± SEM from 3 animals or more or 3 experiments or more, performed in triplicate.

**Results**

**GUCY2C in epithelial cells opposes desmoplasia**

The absence of epithelial GUCY2C signaling in Gucy2c knockout mice (Gucy2c−/−) produced submucosal hypertrophy (Fig. 1A), with canonical characteristics of desmoplasia (1, 2, 5, 7). Specifically, stromal expansion was associated with increased deposition of the matrix components tenasin C (Fig. 1B, top left), fibronectin (Fig. 1B, bottom), and collagen I (Fig. 1B, top right and bottom right), which is a hallmark of malignancy-associated desmoplaysia (37). Also, absence of epithelial GUCY2C signaling increased submucosal fibroblast content, particularly in the pericryptal sheath (Fig. 1C1 and 2), an anatomic location driving mesenchymally-directed epithelial cell proliferation (8, 38). Furthermore, these cells were identified as fibroblasts, reflected by increased transcription (Fig. 1D) and translation (Fig. 1E) of canonical markers of fibroblast activation (1, 2, 5, 7). Thus, this submucosal hypertrophy in Gucy2c−/− mice recapitulated the desmoplastic reaction in human colorectal cancer.

Moreover, in vitro studies with human colon cancer cells and fibroblasts further demonstrated that fibroblast activation is modulated by GUCY2C signaling. Media conditioned by T84 human colon cancer cells in the presence or absence of GUCY2C-activating ligand (ST) were collected and used to treat CCD-18Co human fibroblasts. T84 cells express GUCY2C,
which mediates canonical downstream cGMP signaling upon ligand binding (20–22). In contrast, CCD-18Co cells do not express GUCY2C and are unresponsive to ligands targeting that receptor. As quantified by activated fibroblast numbers (Fig. 2A), matrix synthesis (Fig. 2B), and contraction of collagen (Fig. 2C; refs. 1, 7, 8, 35), conditioned media from T84 cells without ST treatment produced fibroblast activation, which was markedly reduced by ST.

Epithelial GUCY2C regulates fibroblast activation through TGF-β secretion

TGF-β is an established mediator of fibroblast activation and desmoplasia whose secretion characterizes the entire developmental continuum of solid tumors in animals and humans (1, 2, 7, 8, 11). GUCY2C activation by ST did not alter transcription of TGF-β, but markedly increased TGF-β retention and decreased TGF-β secretion, by cancer cells (Fig. 3A and B). In a series of conditioned-media experiments, media conditioned by T84 human colon cancer cells were collected and used to treat CCD-18Co human fibroblasts. Reducing TGF-β mRNA expression and protein secretion in cancer cells with siRNA (Fig. 3A) mimicked ST-induced GUCY2C signaling and opposed fibroblast activation, including collagen contractility and translation of biomarkers of activation, by conditioned media (Fig. 3C and D). Inhibiting fibroblast TGF-β type I receptors with TGF-β receptor inhibitor SB-505124 also mimicked ST-induced GUCY2C signaling and opposed fibroblast activation by conditioned media (Fig. 3E). Furthermore, cancer cell–conditioned media activated fibroblast TGF-β receptor signaling through phosphorylation of the TGF-β signaling target Smad-3, and GUCY2C signaling in cancer cells blocked that effect (Fig. 3F).
conduct in which Smad-3 phosphorylation (Fig. 4B) induced by cancer cell
conditioned media. The effects of neutralizing antibodies on phosphorylation (Fig. 4E), and thickness (Fig. 4C), total collagen deposition (Fig. 4D), Smad-3
the submucosal desmoplasia (Fig. 4C), reducing interstitial
thickness (Fig. 4C), total collagen deposition (Fig. 4D), Smad-3
phosphorylation (Fig. 4E), and fibroblast activation (Fig. 4F). These data reveal that GUCY2C mediates an efferent mucosal
paracrine loop that modulates epithelial TGF-β secretion, fibroblast
activation, and Stromal remodeling by GUCY2C is mediated
through epithelial AKT signaling.

GUCY2C reciprocally regulates fibroblast-dependent epithelial cell hyperproliferation
Beyond the contribution of efferent mucosal signals to submucosal fibroblasts, mechanisms by which this microenvironmen
tal reprogramming reciprocally contributes to an afferent paracrine loop modulating epithelial hyperproliferation
remain incompletely defined (1, 2, 7, 8). To investigate this
afferent loop, we conducted a series of in vitro experiments
using sequentially conditioned media: media conditioned by
human colon cancer cells were collected and used to activate
human fibroblasts, and the media conditioned by these activated fibroblasts were collected and applied to human colon cancer
cells.

In one study, CCD-18Co human fibroblasts were activated by TGF-β at different concentrations, and the conditioned media
were collected. Application of this fibroblast-conditioned media drove proliferation of human colon cancer cells, as
quantified by [3H]-thymidine incorporation, in a TGF-β-concentration–dependent manner (Fig. 6A). Similarly, colon cancer
cell-conditioned media activated fibroblasts, which, in turn, produced conditioned media that reciprocally drove the pro
liferation of HCT116 human colon cancer cells, that do not express GUCY2C or TGF-β receptors (Fig. 6B). However, the
ability of fibroblasts to drive epithelial proliferation was elim
inated by pretreating epithelial cell-conditioned media with TGF-β neutralizing antibodies (Fig. 6B). Furthermore, when
treated with media from cancer cells incubated with the
GUCY2C ligand ST, fibroblasts failed to drive epithelial pro
liferation (Fig. 6B). Exogenous supplementation of fibroblasts
with rTGF-β reconstituted the fibroblast-conditioned media’s
capacity to induce epithelial proliferation, abrogating the
effects of TGF-β neutralizing antibody or GUCY2C signaling
(Fig. 6B). These results reveal that GUCY2C signaling regulates
the epithelial secretion of TGF-β, which not only activates
fibroblasts, but also induces them to release factors that reciprocally feed back to drive epithelial cell proliferation. 

Desmosplastic fibroblast activation is associated with expression of the mitogen HGF (Fig. 1D), a mediator of microenvironmen
tal influences on epithelial cells, including stromal induction of epithelial proliferation (1, 2, 7, 8, 11, 40). In agreement with previous studies, HGF induced HCT116 human colon cancer cells to proliferate in a concentration-dependent fashion (Fig. 6C). Furthermore, pretreatment of

GUCY2C regulates epithelial TGF-β secretion and fibroblast activation through Akt
GUCY2C regulates epithelial cell homeostasis and suppresses tumorigenesis through the Akt signaling pathway
(21). Notably, studies have also demonstrated that Akt regu
lates the secretion of TGF-β in mechanisms remodeling the stroma microenvironment (39). In vitro, elimination of AKT
expression with siRNA (siAkt) mimicked ST-induced GUCY2C
signaling, and replicated the effects of ST on cancer cell
secretion of TGF-β (Fig. 5A) and fibroblast activation (Fig. 5B). Conversely, constitutive activation of AKT by myristoyla
tion (myrAKT; ref. 21) mimicked the absence of GUCY2C
signaling, and blocked the reverting effects of ST, leading to
the promotion of TGF-β secretion (Fig. 5C). Moreover, reduc
ing AKT expression through gene disruption in vivo subdued the stromal remodeling produced by silencing GUCY2C (Fig. 5D). These observations support a model in which, as in other homeostatic processes like proliferation and metabolism (19–
23), the regulation of epithelial TGF-β secretion, fibroblast
activation, and Stromal remodeling by GUCY2C is mediated
through epithelial AKT signaling.
cancer cells with ST reduced HGF mRNA and protein production from fibroblasts that were activated by TGF-β secreted from colon cancer cells, (Fig. 6D). In turn, those fibroblast-conditioned media activated cMET, the canonical receptor for HGF (32), in HCT116 cells. This effect was eliminated by pretreating fibroblast-conditioned media with HGF-neutralizing antibody, an effect reversed by rHGF (Fig. 6E). Moreover, ST-activated GUCY2C signaling in epithelial cells reduced their ability to induce fibroblasts to drive colon cancer cell proliferation (Fig. 6B and F). This effect was replicated by adding...
HGF-neutralizing antibodies or an inhibitor of cMET to the fibroblast-conditioned media and blocked by rHGF (Fig. 6F). These observations suggest a model in which GUCY2C mediates an efferent paracrine circuit regulating the epithelial secretion of TGF-β, and the consequent activation of fibroblasts. In turn, TGF-β ultimately induces a reciprocal afferent paracrine circuit in which the activated stromal fibroblasts produce HGF, which promotes cMET-dependent epithelial cell proliferation (Fig. 7).

Discussion

Undergoing continuous cycles of regeneration, the intestinal crypt-surface axis is dynamic. GUCY2C signaling organizes the spatiotemporal tissue pattern, maintaining homeostasis along this axis (19–23). Specifically, GUCY2C controls epithelial cell proliferation by regulating the expression of critical mediators that slow the cell cycle (19–23). Furthermore, GUCY2C and cGMP signaling establish cell fate by promoting the differentiation of epithelial cells in the secretory lineage, which includes Paneth and goblet cells (19). These effects define the balance between the relative sizes of proliferating and differentiated cell compartments along the crypt-surface axis (19–23). Moreover, GUCY2C is key in matching the appropriate metabolic program to the functional demands along this axis. Namely, low GUCY2C signaling in the crypt favors glycolysis to support rapidly proliferating transit-amplifying cells (21). Conversely, robust GUCY2C signaling in the villus/surface compartment shifts the metabolic program to mitochondrial oxidative phosphorylation, the canonical source for ATP generation in differentiated cells (21).
The present study expands the homeostatic role for GUCY2C beyond these cell-autonomous functions to coordinating the paracrine cross-talk between the epithelial and mesenchymal compartments that is essential for normal tissue patterning (1, 3, 40). Indeed, it suggests a model in which mucosal GUCY2C coordinates bidirectional epithelial–mesenchymal cross-talk in the intestine (Fig. 7). In this model, GUCY2C signaling in the epithelium opposes an efferent mucosal paracrine loop by suppressing the epithelial secretion of TGF-β, the activation of submucosal fibroblasts, and the desmoplastic reaction. In turn, the suppression of fibroblast activation by GUCY2C-regulated paracrine signaling reduces HGF, silencing an afferent loop that drives epithelial cell proliferation. Notably, this GUCY2C function in the intestinal mucosa recapitulates that of the related guanylyl cyclase isoform NPR1 in cardiomyocytes (28, 29). NPR1 coordinates mesenchymal homeostasis in the heart, and its silencing produces cardiac fibrosis that is independent of increases in blood pressure (28, 29). Targeted NPR1 knockout (Npr1−/−) produces local extracellular matrix remodeling in paracrine pathways involving increased TGF-β (28, 29).

The discovery that GUCY2C underlies spatiotemporal patterning along the crypt-surface axis expands its role in the
Figure 6. Myofibroblast HGF production is controlled by epithelial cell GUCY2C and mediates afferent circuits regulating colon cancer cell proliferation. A, TGF-β induces CCD-18Co human fibroblasts to produce paracrine substances in conditioned media driving T84 human colon cancer cell proliferation in a concentration-dependent fashion, quantified by [3H]-thymidine incorporation. B, media conditioned by T84 human colon cancer cells incubated with PBS (control) or ST (1 μmol/L; 48 hours) were treated with control IgG or neutralizing anti-TGF-β monoclonal antibody, with or without replacement with rTGF-β. These media conditioned by T84 cells and processed as described were incubated with CCD-18Co human fibroblasts. Media sequentially conditioned by T84 cells and fibroblasts were then incubated with HCT116 human colon cancer cells that do not express GUCY2C or TGF-β receptors, followed by quantification of proliferation by [3H]-thymidine incorporation. (Before conditioning by fibroblasts, T84 cell-conditioned media were treated with: IgG, control; ST, 1 μmol/L; rTGF-β, depletion of TGF-β by immunoprecipitation followed by replacement with rTGF-β (5 ng/mL).) C, HGF induces HCT116 human colon cancer cell proliferation in a concentration-dependent fashion, quantified by [3H]-thymidine incorporation. D, ST (1 μmol/L; 48 hours) pretreatment attenuates media conditioned by T84 colon cancer cells to induce HGF mRNA (left) and protein (right) expression in CCD-18Co human fibroblasts, quantified by RT-PCR and ELISA, respectively. E, HGF secreted by CCD-18Co human fibroblasts activated by media conditioned by T84 human colon cancer cells treated with PBS or ST (1 μmol/L; 48 hours) activates cMET in HCT116 human colon cancer cells. cMET activation was quantified by immunoblotting for phosphorylation of cMET at Tyr1234/1235. (Before addition to HCT116 colon cancer cells, conditioned media were treated with: IgG, control; HGF nAb, 20 μg/mL; rHGF, depletion of HGF-anti-HGF complexes by immunoprecipitation followed by replacement with recombinant HGF (2.5 ng/mL).) F, HGF secreted by CCD-18Co human fibroblasts activated by media conditioned by T84 human colon cancer cells treated with PBS or ST (1 μmol/L; 48 hours) induces HCT116 colon cancer cell proliferation through cMET. (Before addition to HCT116 colon cancer cells, conditioned media were treated with: IgG, control; HGF Ab, 20 μg/mL; rHGF, depletion of HGF-anti-HGF complexes by immunoprecipitation followed by replacement with recombinant HGF (2.5 ng/mL).) In some experiments, cMET was inhibited by cMET Kinase Inhibitor III (500 nmol/L; cMET Inhibitor). Processed media were then incubated with HCT116 human colon cancer cells, followed by quantification of proliferation by [3H]-thymidine incorporation. Data in 6A, 6B, 6C, and 6F are representative of 3 or more experiments. Data in D and E represent means of n = 3 experiments ± SEM. *P < 0.05; **P < 0.01; NS, not significant.
homeostatic maintenance of the intestinal mucosae (19, 22). Moreover, it highlights the emergence of GUCY2C as a tumor suppressor universally silenced in the initiation and progression of colorectal cancer (20, 21, 23). The endogenous ligands for GUCY2C, guanylin and uroguanylin, are the most commonly lost gene products in intestinal tumorigenesis and these ligands are lost at the earliest stages of transformation (24–27). Loss of paracrine ligands silences GUCY2C, which, in turn, activates AKT and mTOR, well-established oncogenes driving tumorigenesis in many tissues (21). Indeed, eliminating GUCY2C signaling amplifies intestinal tumorigenesis induced by carcinogens or gene mutations (20).

Silencing GUCY2C establishes a number of cell-autonomous mechanisms underlying epithelial cell tumorigenesis (6). Thus, the cell cycle is accelerated, expanding the proliferating crypt compartment (19–23). Furthermore, metabolic programming is shifted from mitochondrial oxidative phosphorylation to aerobic glycolysis characterizing the Warburg metabolic phenotype (21). Moreover, genomic instability is accelerated by overproduction of reactive oxygen species and exacerbated by a decrease in the ability to repair DNA damage (20, 21). Indeed, eliminating GUCY2C signaling induces Apc loss of heterozygosity in Apc\textsuperscript{min} mice and the acquisition of mutations in β-catenin in mice treated with the carcinogen AOM, encompassing the genomic changes underlying nearly all sporadic intestinal tumorigenesis in humans (20). The present study expands the role of GUCY2C as a tumor suppressor whose silencing not only corrupts cell-autonomous pathways regulating epithelial transformation, but also epithelial–mesenchymal paracrine circuits underlying fibroblast activation and desmoplasia, a process that universally contributes to tumorigenesis in most tissues (2, 5, 6).

Although interactions between tumor cells and the desmoplastic stroma are essential for cancer progression, invasion, metastasis, and the evolution of therapeutic resistance, the relative contributions of each compartment to tumor initiation remain undefined (1, 2, 5, 16). The oncogenic model of cancer suggests that tumors initiate and evolve by accumulating mutations, which alter critical signaling pathways regulating cell-autonomous homeostatic functions, which ultimately leads to genomic instability and acquisition of invasive and metastatic phenotypes (6, 41–43). In this model, the mesenchymal compartment is dependent and reactive and shaped by the epithelial tumor to support cancer evolution. An alternate hypothesis suggests that, in some cases, stroma could be the pathophysiologic initiator of tumorigenesis in dependent normal epithelial cells. Mice in which TGF-β receptors are silenced selectively in stromal fibroblasts develop neoplasia in the prostate and stomach (10, 44). Similarly, genetic models of HGF overexpression in fibroblasts are characterized by mammary tumorigenesis (45). In addition, mutations of tumor suppressor genes in stromal fibroblasts drive the development of prostate tumors (46). This mechanistic debate about which compartment “leads” transformation has not yet been resolved (2, 5). The present study, in the context of GUCY2C silencing as one of the earliest changes underlying intestinal neoplasia (24–27), suggests that epithelial cell transformation leads tumor initiation in intestine by corrupting cell-autonomous (19–23) and non–cell-autonomous homeostatic pathways, including the promotion of desmoplasia in colorectal cancer.

Beyond this question of compartmental hierarchy, the relationship between canonical networks whose corruption initiates neoplasia, and reciprocal paracrine signaling axes organizing epithelial–mesenchymal cross-talk producing desmoplasia, remains undefined. For example, nearly all sporadic colorectal tumors harbor mutations in the WNT signaling pathway, primarily in APC (about 80%) or β-catenin (about 15%), which drive cell-autonomous changes in epithelium (41, 43, 47). However, the precise linkages between corrupted WNT signaling pathways underlying tumorigenesis and mechanisms coordinating desmoplasia characterizing colorectal cancer remain unknown. The present study offers a mechanistic explanation for coordination of epithelial transformation and the development of the desmoplastic reaction in colorectal cancer. Indeed, silencing GUCY2C in epithelial cells seems to be one of the earliest universal changes in colorectal carcinogenesis (24–27), with the ability to promote genomic instability and mutations in WNT signaling pathway.
intermediates (20). In this model, silencing the GUCY2C tumor suppressor early in transformation corrupts cell-autonomous functions that are essential for transformation, including proliferation, metabolism, and DNA damage and repair (19–23). Moreover, the present study reveals that silencing GUCY2C simulates the AKT-dependent paracrine signaling through increased epithelial cell TGF-β secretion, activating fibroblasts that reshape the mesenchymal matrix compartment, producing the desmoplastic reaction promoting colorectal tumor invasion and progression.

There continues to be intense interest in elucidating the precise compartmental contributions, and their sequence, underlying epithelial–mesenchymal cross-talk contributing to neoplasia (16). Deconvoluting this spatiotemporal signaling sequence could provide therapeutic targets that disrupt the mutually reinforcing intercompartmental cycle essential for tumor initiation, progression, invasion, and metastasis (1, 2, 4, 5, 8, 16). This challenge is underscored by the incompletely understood role of TGF-β in tumorigenesis, sometimes referred to as the “TGF-β Paradox” (11, 48–49). On the one hand, TGF-β has potent antiproliferative properties in epithelial cells, and silencing tumor cell TGF-β receptors by mutation is a key genomic event mediating progression of colorectal tumorigenesis (41). On the other hand, TGF-β is one of the most potent drivers of quiescent fibroblast transformation to the fibroblast phenotype, although the precise compartment producing this cytokine driving desmoplasia remains uncertain (1, 2, 5, 8). Moreover, the activity of TGF-β on the stroma can promote tumor initiation, progression, and metastasis (50). Similarly, although HGF, which drives epithelial proliferation through cMET, is produced by fibroblasts in desmoplasia, the events inducing that production remain uncharacterized in most tumors (1, 2, 5, 8). In that context, the present study provides insight into the spatiotemporal sequence of signaling interactions coordinating events that drive tumor initiation and progression in epithelia and stroma in colorectal cancer. It suggests a model in which the earliest stages of tumorigenesis initiate, at least in part, by silencing GUCY2C, reflecting loss of ligand expression (24–27). Eliminating cGMP signaling in intestinal epithelial cells not only drives cell-autonomous changes coincident with transformation (19–23), but also amplifies epithelial secretion of TGF-β, creating a cesternal signal driving fibroblast activation and desmoplasia in adjacent stroma. In turn, fibroblasts activated by epithelial cell TGF-β produce HGF, creating a reciprocal afferent cytokine circuit with the potential to signal back to the epithelial compartment through cMET. In more advanced stages of transformation, characterized by loss of TGF-β signaling and its cell-cycle suppression in epithelia (41, 48, 49), the potential of this reciprocal afferent HGF circuit is realized, further amplifying proliferation driving the progression of tumorigenesis.

Epithelial cell GUCY2C signaling is one component of a program establishing and maintaining the intestinal crypt-surface axis through continuous waves of physiologic regeneration. Beyond this role in normal tissue patterning, loss of guanylin and uroguanylin at the earliest stages of premalignancy suggests a novel model of intestinal tumorigenesis, initiating as a disease of tissue-specific paracrine hormone insufficiency (24–27). The resultant silencing of the GUCY2C tumor suppressor produces maladaptive amplification of survival circuits producing DNA damage and mutations contributing to the cell-autonomous basis of colorectal cancer (19–23). Moreover, these changes in epithelial transformation are coordinated with simultaneous changes in cytokine signaling mediating the desmoplastic reaction that, reciprocally, drives epithelial proliferation. This unique model of intestinal transformation as a paracrine hormone deficiency coordinating epithelial–mesenchymal transformation has substantial implications for the prevention and treatment of colorectal cancer. Indeed, GUCY2C is overexpressed by intestinal tumors compared with normal adjacent tissues (36). Early loss of hormones with compensatory overexpression of receptors offers a unique therapeutic window preceding the corruption of epithelial survival pathways and stromal reactivity to prevent maladaptive reprogramming and the evolution of cancer through oral GUCY2C hormone replacement therapy (25). These considerations highlight the potential translational opportunities for oral GUCY2C paracrine hormone supplementation as a novel strategy that could contribute to the prevention of colorectal cancer, underscored by the recent FDA approval and commercial availability of GUCY2C ligands to treat chronic constipation (51).

Disclosure of Potential Conflicts of Interest
S. A. Waldman received commercial research grant from Targeted Diagnostics & Therapeutics, Inc. and other commercial research support from Merck. No potential conflicts of interest were disclosed by the other authors.

Authors’ Contributions
Conception and design: A. V. Gibbons, J. E. Lin, P. Li, E. S. Blomain, S. Rattan, A. E. Snook, S. Schulz, S. A. Waldman
Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.): A. V. Gibbons, J. E. Lin, G. W. Kim, G. P. Marszalowicz, R. A. Stoecker, E. S. Blomain, S. Rattan
Analysis and interpretation of data (e.g., statistical analysis, biostatistics, computational analysis): A. V. Gibbons, J. E. Lin, G. W. Kim, E. S. Blomain, S. Rattan, A. E. Snook, S. Schulz, S. A. Waldman
Writing, review, and/or revision of the manuscript: A. V. Gibbons, J. E. Lin, G. W. Kim, G. P. Marszalowicz, E. S. Blomain, S. Rattan, A. E. Snook, S. Schulz, S. A. Waldman
Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases): A. V. Gibbons, J. E. Lin, P. Li
Study supervision: A. V. Gibbons, J. E. Lin, P. Li, S. Schulz, S. A. Waldman

Grant Support
These studies were supported by grants from the NIH (R01 CA75123, R01 CA95026, R01 CA146033, P30 CA56036, and R01 CA170533), the Pennsylvania Department of Health (SAP #1400059197 and SAP #1400051723), and Targeted Diagnostic and Therapeutics Inc. The Pennsylvania Department of Health specifically disclaims responsibility for any analyses, interpretations, or conclusions. A. V. Gibbons was supported by an NIH Minority Supplement (R01-CA095026-04S1). J. E. Lin was supported by NIH institutional award T32 GM08562 for Postdoctoral Training in Clinical Pharmacology and is the recipient of the Young Investigator Award from the American Society for Clinical Pharmacology and Therapeutics (ASCPST). G. W. Kim is the recipient of the Graduate Award for Integrative Research in Pharmacology from the American Society for Pharmacology and Experimental Therapeutics (ASPET). P. Li was enrolled in the NIH-supported institutional K30 Training Program in Human Investigation (K30 HL005452) and was supported by NIH institutional award T32 GM08562 for Postdoctoral Training in Clinical Pharmacology. A. E. Snook is the recipient of the Measey Foundation Fellowship.
