ABSTRACT

No targeted treatments are currently approved for HER2 exon 20 insertion-mutant lung adenocarcinoma patients. Mobocertinib (TAK-788) is a potent irreversible tyrosine kinase inhibitor (TKI) designed to target human epidermal growth factor receptor 2 (HER2/ERBB2) exon 20 insertion mutations. However, the function of mobocertinib on HER2 exon 20 insertion-mutant lung cancer is still unclear. Here we conducted systematic characterization of pre-clinical models to understand the activity profile of mobocertinib against HER2 exon 20 insertions. In HER2 exon 20 insertion mutant cell lines, the IC\textsubscript{50} of mobocertinib was higher than poziotinib and comparable or slightly lower than afatinib, neratinib, and pyrotinib. Mobocertinib had the lowest HER2 exon 20 insertion IC\textsubscript{50} / WT EGFR IC\textsubscript{50} ratio, indicating that mobocertinib displayed the best selectivity profile in these models. Also, mobocertinib showed strong inhibitory activity in HER2 exon 20\textsuperscript{YVMA} allograft and patient-derived xenograft models. In genetically engineered mouse models, HER2 exon 20\textsuperscript{G776>VC} lung tumors exhibited a sustained complete response to mobocertinib, while HER2 exon 20\textsuperscript{YVMA} tumors showed only partial and transient response. Combined treatment with a second antibody-drug conjugate (ADC) against HER2, ado-trastuzumab emtansine (T-DM1) synergized with mobocertinib in HER2 exon 20\textsuperscript{YVMA} tumors. In addition to the tumor cell autonomous effect, sustained tumor growth control derived from M1 macrophage infiltration and CD4\textsuperscript{+} T cell activation. These findings support the ongoing clinical development of mobocertinib (NCT02716116) and provide a rationale for future clinical evaluation of T-DM1 combinational therapy in HER2 exon 20\textsuperscript{YVMA} insertion-mutant lung adenocarcinoma patients.
This study elucidates the potent inhibitory activity of mobocertinib against HER2 exon 20 insertion-mutant lung cancer and the synergic effect of combined mobocertinib and T-DM1, providing a strong rationale for clinical investigation.
INTRODUCTION

Lung cancer remains a major threat to public health, with an estimated 230,000 new cases and 140,000 deaths in the United States in 2020 (1). Non–small cell lung cancer (NSCLC) represents the major subtype of lung cancer, with adenocarcinoma the predominant histology. In the past few decades, several oncogenes have been characterized as driver mutations in NSCLC (2). Subsequent development of pharmacologic agents targeting these mutations, such as epidermal growth factor receptor (EGFR) and anaplastic lymphoma kinase (ALK), have led to tremendous clinical benefits for patients (3).

Despite these advances, many driver mutations still do not have targeted agents, indicating the need for novel therapeutic strategies. Among these are alterations in human epidermal growth factor receptor 2 (HER2/ERBB2), an essential gene harbored by 2% to 3% of lung adenocarcinoma (4-8). Most of these mutations occur in the exon 20 as in-frame insertion of with the duplication of amino acids YVMA being the most prevalent (77-100%) (4-7). Considering the large number of lung cancer patients (estimated 230,000 new cases in 2020), it is extremely important to investigate potential treatment strategies for HER2-mutant lung adenocarcinoma (1). Although several clinical trials have tested HER2-targeting tyrosine kinase inhibitors (TKIs), such as poziotinib, afatinib, neratinib, and pyrotinib, only poziotinib have shown some clinical benefits in lung cancer and currently there are no approved therapies (9-12). Therefore, HER2 exon 20 insertion–mutant NSCLC represents an urgent unmet clinical need.
Mobocertinib is a potent EGFR and HER2 TKI currently under investigation against exon 20 insertions. In a phase 1/2 clinical trial, NSCLC patients with EGFR exon 20 insertions showed promising responses to mobocertinib with an objective response rate of 43% (13,14). However, the activity of mobocertinib on HER2 exon 20 insertions is still unclear and requires further investigation.

We utilized systemic pre–clinical models to study how tumors harboring HER2 exon 20 insertions respond to mobocertinib. We also investigated acquired resistance mechanisms to mobocertinib and utilized combination treatments to overcome these mechanisms. Importantly, HER2 exon 20 YVMA insertion tumors showed a potent and sustained response to the combination of mobocertinib and ado-trastuzumab emtansine (T–DM1). In addition to tumor cell autonomous effect, the infiltration of M1 macrophages and the activation of CD4+ T cells are potential mechanisms involved in the combinational therapy.

**MATERIALS AND METHODS**

**Cell Culture**

H1781 and A431 cells were obtained from American Type Culture Collection (ATCC), and HER2 exon 20 insertion–mutant Ba/F3 cells were generated using lentiviral vectors. All cell lines were cultured in RPMI 1640 (Gibco) supplemented with 10% fetal bovine serum (FBS) and incubated in a humidified chamber with 5% CO₂.

**Cell Proliferation Assay**
Cells were plated in 96-well dishes at a certain density (3–5 x 10^3/well). Compound was added to the cells in serial dilution in culture medium to achieve indicated concentration after 24 hours' incubation. Compounds at each dilution were evaluated in triplicate and cells treated with DMSO (1% final concentration) served as the untreated control. MTS-based cholecystokinin-8 (CCK-8; Cat#CK04, Dojindo) assay was used for the measurement and absorption at 450 nm was detected 2–4 hours after adding CCK-8 into the culture medium.

Western Blot

Cells were re-suspended with cold phosphate-buffered saline (PBS) to wash out the medium and then collected by centrifuging at 3000 rpm, 4 °C. Protease and phosphatase inhibitor cocktail (Thermo Fisher Scientific, Cat#78440) was added into RIPA lysis buffer (Thermo Fisher Scientific, Cat#89900) used for the protein extraction and the concentration was measured by a BCA protein assay kit (Thermo Fisher Scientific, Cat#23225). After normalizing the protein concentration, loading buffer was added and the samples were heated at 95 °C for 7 minutes. All the samples were loaded to 4%–20% gradient gel SDS-PAGE with the same volume and the gel was transferred to a nitrocellulose membrane (Bio-Rad, Cat#1704271), which would be blocked in blocking buffer (LICOR, Cat#927-50003) for 1 hour at room temperature. Then, antibodies were added and incubated overnight at 4 °C (Cell Signaling, HER2, Cat#2165S; Phospho-HER2, Cat#2243S; AKT, Cat#4691L; Phospho-AKT (Ser473), Cat#4060; Erk1/2, Cat#9102; Phospho-ERK1/2, Cat#9101). Antibodies were diluted into the indicated concentration according to the instructions with blocking buffer.
supplemented with 0.01% Tween 80. On the following day, TBST (TBS with 0.1% Tween 80) was used to wash the membrane 4 times (7 minutes/wash) to wipe out the antibodies and the membrane was incubated with the second antibody (LICOR, anti-Rabbit, Cat#925-32213; anti-Mouse, Cat#925-68072) for 1 hour at room temperature. Finally, we used TBST to wash the membrane 3 times (7 minutes/time) and TBS 1 time (7 minutes/time) and imaged the membrane using the Odyssey Classic Infrared Imaging System.

**Colonies Formation Assay**

Single-cell suspension was produced and plated in a 6-well cell culture dish (5000 cells/well). Medium containing DMSO or Mobocertinib was changed every 2 days. Cells were cultured for 11 days and fixed with 100% ethanol for 7 minutes. Crystal violet 0.5% (dissolved in 20% methanol) was used for staining and the cells were stained for 5 minutes. After washing, images were taken and ImageJ was used for quantification.

**Ba/F3 Allograft Experiment**

Ba/F3 cells expressing HER2 exon 20^{YVMA} insertion mutation were cultured in RPMI1640 medium supplemented with 10% FBS and incubated at 37 °C with 5% CO₂.

On the day of implantation, cells were harvested, re-suspended in serum-free RPMI 1640 and a 100 μL cell suspension (10^7 cells) was implanted subcutaneously in the right flank of female severe combined immunodeficiency (SCID) mice. All mice were weighed prior to dosing and throughout the study once daily. The tumors were measured in 2 dimensions (length and width) at least twice per week with a caliper in...
millimeters. Tumor volume (mm$^3$) was calculated with the following formula: tumor volume = L x W$^2$ x 0.5.

**PDX Experiment**

The patient-derived xenograft ST3107 (START, TX, USA) was derived from a primary NSCLC tumor bearing the HER2 exon20 insertion YVMA. ST3107 tumor fragments (5 x 5 x 5mm) were implanted subcutaneously in the right flank of 7-week old female Athymic Nude, Outbred Homozygous mice (Jackson Laboratory); all experiments were conducted at START (TX, USA). When the mean tumor volume (MTV) MTV reached approximately 150-250 mm$^3$, the animals were randomized into treatment groups and dosing was initiated on Day 0 with mobocertinib or vehicle orally administered daily. Tumor size and body weight were measured twice weekly and the MTV was calculated using the formula (0.5 × [length × width$^2$]).

**Mouse Generation**

The chicken beta-actin (pGK) promoter, a loxP flanked STOP cassette, and human HER2 with exon 20 insertion sequences of G776>VC were inserted into the mouse collagen A1 locus. Sequence-verified targeting vectors were co-electroporated with an FLPe recombinase plasmid into C10 C57BL/6J embryonic stem cells (Mirimus). Then, transgene-positive embryonic stem clones were injected into C57BL/6 blastocysts, and the resulting chimaeras were mated with wild-type mice to determine germline transmission of G776>VC transgene. Upon Cre-mediated recombination, the STOP cassette was excised promoting expression of the mutant HER2 protein. The mouse
gDNA was used as PCR template and the hHER2ex20ins GVC sequence was confirmed with Sanger sequencing. The genotyping primers used are: HER2-forward: CAGATGCGGATCCTGAAAGAG and HER2-reverse: CCAGCCCGAAGTCTGTAATTT.

The detailed strategy was previously described (15). All animal experiments, including breeding and treatment studies, were performed with approval of the NYU Langone Medical Center Institutional Animal Care and Use Committee.

**GEMM Treatment Studies**

*HER2* exon 20^{G776>VC} mice were monitored by MRI for tumor development after intranasal induction with adeno-Cre (5×10^7 pfu). Tumor-bearing mice were dosed with mobocertinib (30 mg/kg, orally [PO], daily) and monitored by MRI every 2 weeks.

*HER2* exon 20^{YVMA} mice were fed a continuous doxycycline diet from 6 weeks of age. Mice were evaluated by MRI imaging to quantify lung tumor burden before and after drug treatment. Mice with equal initial tumor volume were nonblindly randomized to the following groups: vehicle control, mobocertinib (30 mg/kg, PO, daily), T–DM1 (10 mg/kg, tail vein, once every week), combination of mobocertinib (30 mg/kg, PO, daily), and T–DM1 (10 mg/kg, tail vein, once every week), alisertib (20 mg/kg, PO, daily), combination of mobocertinib (30 mg/kg, PO, daily) and alisertib (20 mg/kg, PO, daily), sapanisertib (0.3 mg/kg, PO, daily), combination of mobocertinib (30 mg/kg, PO, daily) and sapanisertib (0.3 mg/kg, PO, daily). For macrophage-depletion experiments, Clodrosome was administered to mice via tail vein (intravenously) at 50 mg/kg. The first
dosage was conducted 2 days before treatments with 200 μl followed by 100 μl per mouse twice a week.

Progression-free survival (PFS) was analyzed based on the standard criteria in clinical trials. Briefly, PFS was the duration between treatment start and progression, which was defined by increase of tumor size compared with the previous scan of MRI or the appearance of new lesions.

**MRI Quantification**

Mice were anesthetized with isoflurane to perform lung MRI using the BioSpec USR70/30 horizontal bore system (Bruker) to scan 24 consecutive sections. Tumor volume within the whole lung was quantified using 3-D slicer software to reconstruct MRI volumetric measurements, as described previously (16). Acquisition of the MRI signal was adapted according to cardiac and respiratory cycles to minimize motion effects during imaging.

**Immunohistochemistry Staining and Multi-immunofluorescence**

Mice were euthanized and lung tissues were collected and fixed with 10% formalin. IHC staining and multi-immunofluorescence (IF) were performed in iHisto Inc, Salem, Massachusetts, using the following antibodies: TTF1 (Epitomics, 5883-1), p63 (Abcam, ab53039), Phospho-HER2 (Tyr1221/1222; Cell Signaling Technology, #2243), HER2 (Cell Signaling Technology, #2165), Phospho-ERK1/2 (Thr202/Tyr204; Cell Signaling Technology, #9106).
Technology, #4370) and F4/80 (Cell Signaling Technology, #70076 for IHC and #30325 for IF). ImageJ was used for the quantifications of all IHC staining.

**RNA-seq and Data Analyses**

RNA-Seq on vehicle and treated nodules were performed in NYU Langone Health Genome Technology Core. Reads were aligned to the reference genome using STAR (17). R (version 4.0.2) and DESeq2 package (version 1.28.1) were utilized for differential gene expression analysis (18).

Gene expression levels were quantified and estimated using RSEM (19). GSEA (version 4.1.0) and Hallmarker gene set were used for the gene set enrichment analysis based on TPM. Pathways with $P$ value < 0.05 and FDR < 0.25 were considered significantly enriched.

Dot plots of enriched pathways, heat maps of genes, and volcano plots were generated using the Pheatmap, ggplot2, and EnhancedVolcano in R (version 4.0.2).

**In Vitro Cell Line Flow Cytometry**

Cells were plated on tissue culture dishes. Indicated concentrations of compound were added into medium the next day. After 6 hours of treatment, cells were collected as cell suspension and filtered through 70-μm cell strainer (Thermo Fisher Scientific). Then, cells were stained with a LIVE/DEAD Fixable Aqua Dead Cell Stain Kit (Molecular Probes) and resuspended in PBS supplemented with 2% FBS. Anti-human HER2
antibody (clone 24D2, BioLegend) was used to estimate the HER2 level on the cell surface. Cells were imaged on a BD Bioscience LSRFortessa and analyzed with FlowJo software.

Tumor-infiltrating Immune Cell Isolation and Flow Cytometry Analysis
Mice were euthanized, and lungs were perfused with sterile PBS through heart perfusion from the left ventricle after collection of bronchoalveolar lavage (BAL) fluid. Whole lung was minced and digested in collagenase D (11088866001, Roche) and DNase I (10104159001, Roche) in Hank’s Balanced Salt Solution at 37 °C for 30 minutes. After incubation, digested tissue was filtered through a 70-μm cell strainer (Thermo Fisher Scientific) to obtain single-cell suspensions. Separated cells were treated with 1 × RBC lysis buffer (BioLegend) to lyse red blood cells. Live cells were determined with a LIVE/DEAD Fixable Aqua Dead Cell Stain Kit (Molecular Probes). Cell pellets were resuspended in PBS with 2% FBS for FACS analysis. Cells were stained with the indicated cell-surface markers and fixed/permeabilized using a Fixation/Permeabilization Kit (eBioscience). Cells were imaged on a BD Biosciences LSRFortessa and analyzed with FlowJo software. The gating strategy was described previously (20).

Flow Antibodies
Isolated lung infiltrating immune cells were stained with fluorescently labeled anti-mouse antibody CD45 (clone 30-F11, BioLegend), CD3 (clone 17A2, BioLegend), CD49b (clone DX5, BioLegend), CD19 (clone 6D5, BioLegend), CTLA-4 (clone UC10-4B9,
Invitrogen), CD69 (clone H1.2F3, BioLegend), TIM3 (clone RMT3-23, Invitrogen),
FOXP3 (clone FJK-16s, eBioscience), PD-1 (clone 29F.1A12, BioLegend), KI-67 (clone
16A8, BioLegend), CD4 (clone GK1.5, BioLegend), CD8 (clone 53-6.7, BioLegend), H-2
(clone M1/42, BioLegend), Ly6G (clone 1A8, BioLegend), CD103 (clone 2E7,
BioLegend), F4/80 (clone BM8, BioLegend), CD86 (clone GL-1, BioLegend), PD-L1
(clone 10F.9G2, BioLegend), Ly6C (clone HK1.4, BioLegend), CD206 (clone C068C2,
BioLegend), CD11B (clone M1/70, BioLegend), CD11C (clone N418, BioLegend), CD4
(clone RM4-4, BioLegend), CD8 (clone 53-6.7, BioLegend), GZMB (clone GB11, BD
Horizon), CD62L (clone MEL-14, BioLegend), and CD44 (clone IM7, BioLegend).

**Statistical Analysis**

Student’s t test (2-tailed) was utilized for statistical analysis in GraphPad Prism (Version
8) and Kaplan-Meier method was used for PFS under log-rank (Mantel-Cox) test. A P
value of less than 0.05 was set as significant and standard error of the mean (SEM) was
used for the error bars.

**RESULTS**

**HER2 Exon 20 Insertion Mutations are Sensitive to Mobocertinib**

We first tested the ability of mobocertinib to inhibit HER2 exon 20 insertions in vitro. Cell
lines harboring insertion mutations of HER2 exon 20, which are located in the tyrosine
kinase domain were utilized for in vitro testing, including HER2 A775_G776insYVMA
(YVMA), G776>VC, and P780_Y781insGSP (GSP). Ba/F3 cell line is a commonly
utilized system for investigating kinases signaling and targeted inhibitors in *EGFR* and *HER2* mutant lung cancer (21,22). Mobocertinib showed a higher half-maximal inhibitory concentration (IC$_{50}$) than poziotinib, comparable or slightly lower than afatinib, neratinib, or pyrotinib, and much lower than osimertinib on Ba/F3 *HER2* exon 20 insertion mutant cell lines (Figure 1A). Of note, we observed that different types of *HER2* exon 20 insertion mutations responded differently to mobocertinib. In our case, *HER2* exon 20$^{YVMA}$–mutant cell lines have higher IC$_{50}$ than *HER2* exon 20$^{G776>VC}$ and *HER2* exon 20$^{GSP}$ cell lines (Figure 1A). This indicated that *HER2* exon 20 insertion mutations are sensitive and may respond distinctively to mobocertinib. In addition, we performed an IC$_{50}$ experiment on the H1781 cell line, a human lung adenocarcinoma cell line with *HER2*$^{G776>VC}$ deletion insertion. Consistent with in Ba/F3 cell lines, mobocertinib has a moderate IC$_{50}$ (0.12 μM), which is less potent than poziotinib, similar to afatinib, and more effective than osimertinib in H1781 (Figure 1B).

Next, we explored the effect of mobocertinib and other TKIs on wild type (WT) *EGFR*, as its inhibition is the main contributor of clinical toxicity with skin rash and diarrhea observed. The WT *EGFR* dependent A431 was used as the study model to investigate the WT *EGFR* inhibition. Compared with other TKIs in the class, mobocertinib has a moderate IC$_{50}$ against WT *EGFR* and poziotinib has an extremely low IC$_{50}$ against WT *EGFR*, which is almost 50 times lower than that of mobocertinib (Supplementary Figure S1A). We used the ratio of the *HER2* insertion mutation IC$_{50}$ to WT *EGFR* IC$_{50}$, which is able to demonstrate the extent of selectivity on mutant *HER2* rather than WT *EGFR*. We found that mobocertinib had the lowest ratio of all three *HER2* exon 20
insertion mutations compared with osimertinib, poziotinib, afatinib, neratinib, and pyrotinib, showing selective sensitivity on HER2 exon 20 insertion mutations (Figure 1C). In contrast, poziotinib had relatively high ratios on all three HER2 exon 20 insertion–mutant cell lines, consistent with the reported toxicity in the clinics (23). While mobocertinib presented a manageable safety profile, it was observed a higher incidence of gut toxicity rather than traditional skin rash reported with other TKIs.

HER2 signaling in H1781 and Ba/F3-HER2 exon 20YVMA mutant cell lines was inhibited by mobocertinib at 0.1 μM with significantly decreased phosphorylations of HER2, AKT, and ERK1/2 in a dose-dependent fashion (Figures 1D and 1E). We performed a colony formation assay using the H1781 cell line, and found that mobocertinib significantly inhibited the growth of H1781 cells at 0.01 μM (Figure 1F and Supplementary Figure S1B). To understand the inhibitory profile of mobocertinib, Ba/F3-HER2 exon 20YVMA cell line were implanted subcutaneously in mice, and dosed with vehicle, 50 milligrams per kilogram (mpk), or 100 mpk of mobocertinib for 7 days. Mobocertinib (50 mpk) was able to inhibit the tumor, and a higher dosage (100 mpk), induced tumor regression (Figure 1G). Although we observed body weight loss (Supplementary Figure S1C) in the 100 mpk treated mice, this was manageable (less than 20%) and had no effect on their general health in the long-term monitoring.

Furthermore, we used the patient-derived xenografts (PDX) ST31 harboring HER2 exon 20YVMA. Mobocertinib showed robust antitumor efficacy (Figure 1H) and was well
tolerated. These data indicate that HER2 exon 20 insertion mutant cell lines and subcutaneous models (exon 20^{YVMA}) including PDX can be inhibited by mobocertinib.

**HER2 Exon 20^{G776>VC} GEMM Showed Sustained Response to Mobocertinib**

We next tested mobocertinib in orthotopic lung cancer genetically engineered mouse models (GEMMs) to better evaluate cognate human malignancies with tissue-specific immunity. GEMM harboring human HER2 exon 20^{G776>VC} mutation was generated using the LoxP-STOP-LoxP system for the first time. We intranasally delivered adeno-Cre virus into adult HER2 Exon 20^{G776>VC} mice to initiate HER2 exon 20^{G776>VC} expression specifically in murine lung epithelial cells (Figure 2A). Magnetic resonance imaging (MRI) showed that lung tumors appeared 8 weeks after viral delivery (Figure 2B). According to immunohistochemistry (IHC), HER2 exon 20^{G776>VC} GEMM tumors were confirmed as adenocarcinoma histology with a strong positive staining of adenocarcinoma markers TTF1 and SPC, along with a negative squamous cell carcinoma marker p63 (Figure 2C).

In the HER2 exon 20^{G776>VC} mutant GEMM model, mobocertinib dosed at 30 mpk demonstrated a rapid tumor regression after just 2 weeks of treatment with close to complete response after 4 weeks of treatment (Figure 2D and Supplementary Figure S2A). Sustained response was observed through up to 16 weeks of treatment monitoring (Figure 2E). In addition, 3 days of daily mobocertinib treatment was sufficient to completely abolish HER2 downstream signaling as monitored by
phosphorylated-ERK1/2 staining of HER2 exon 20^{G776>VC} tumors (Supplementary Figure S2B).

HER2 Exon 20^{YVMA} GEMM Initially Responded to Mobocertinib but Became Acquired Resistant upon Continuous Treatment

In addition to the HER2 exon 20^{G776>VC}–mutant GEMM model, we employed another mouse model with a HER2 exon 20^{YVMA} mutation that was previously generated (24). We investigated the effects of mobocertinib on HER2 exon 20^{YVMA}–insertion tumors. Partial response of about 30% tumor shrinkage was seen after 4 weeks of mobocertinib treatment (Figure 3A and Supplementary Figure S2C). IHC results confirmed that a 3 day treatment of mobocertinib effectively abolished p-HER2 and inhibited its major downstream signaling target p-ERK, while a significant increase of total HER2 was also seen (Figure 3B-D), supporting the on-target efficacy of mobocertinib against HER2 exon 20^{YVMA} in vivo. When we continued the treatment for 6-8 weeks, tumors then relapsed. We stained IHC on the relapsed tumors for total HER2, p–HER2, and p–ERK1/2. This showed significantly higher levels of p–ERK1/2 and p–HER2, along with an increase in total HER2 expression compared with treatment at 3 days (Figure 3B-D).

These data suggest that mobocertinib showed potent on-target efficacy in both HER2 exon 20^{G776>VC} and HER2 exon 20^{YVMA} GEMMs, but had differential outcomes after long term treatment.
Pathways Enriched in HER2 Exon 20YVMA Acquired Resistant Tumors

To compare mobocertinib acquired resistance (continuous treatment and confirmed relapse by MRI) and early response (3 days of treatment) on HER2 exon 20YVMA tumors (three mice each), and probe pathways leading to acquired resistance, we performed bulk RNA–sequencing on tumor nodules from HER2 exon 20YVMA tumor–bearing mice. Using Gene Set Enrichment Analysis (GSEA), we found that 15 pathways of the Hallmark gene set were significantly enriched in acquired resistant tumors as determined by cutoff value (P value < 0.05 and false discovery rate [FDR] <0.25) (Figure 4A and Supplementary Table S1). Three of them enlightened us to the candidates for combinational therapies, which are “G2M Checkpoint” (NES = 2.10; NOM p-value = 0; FDR q-value =0), “Mitotic Spindle” (NES = 1.89; NOM p-value = 0; FDR q-value = 0.001) and “mTORC1 Signaling” (NES = 1.34; NOM p-value = 0.008; FDR q-value = 0.096) (Figure 4B-D). Also, significantly differentially expressed (P value < 0.05) genes involved in these three pathways were listed in Supplementary Figure S3A-C. To note, no second mutations and/or amplification on HER2 site were detected based on the Sanger sequencing and quantitative PCR of HER2 in genomic DNA extracted from treatment-naive and acquired resistant tumors (Supplementary Figure S3D-E).

Mobocertinib Increases HER2 Expression at the Cell Membrane

It is worth noting that total HER2 protein level increased when treated with mobocertinib both on H1781 and Ba/F3-HER2 exon 20YVMA cell lines (Figures 1D and 1E) and on HER2 exon 20YVMA tumors (Figure 3B). To further delineate if HER2 expression...
increased on cell surface, flow cytometry was performed on H1781 and Ba/F3-HER2 exon 20YVMA cell lines. When treated with various concentrations of mobocertinib for 6 hours, both cell lines showed significantly higher level of HER2 mean fluorescent intensity compared to control (Figures 4E and 4F). Using reverse transcription polymerase chain reaction (RT-PCR), we showed that HER2 mRNA levels increased with treatment after 6 hours (Figure 4G). In addition, from RNA–sequencing result, mobocertinib–treated nodules showed elevated HER2 transcripts per million (TPM) (Supplementary Figure S3F).

Mobocertinib and T–DM1 is the Most Effective among All Three Combinations

Based on the pathway analysis described above and the increasing level of HER2 on cell surface, 3 candidate drugs were further assessed for potential synergy with mobocertinib: alisertib (aurora kinase A inhibitor), sapanisertib (mammalian target of rapamycin [mTOR] inhibitor), and T–DM1 (HER2 ADC). Aurora kinase A is involved in the G2/M process and mitotic spindle assembly and in regulating resistance to EGFR TKI (25). Sapanisertib acts through inhibition of the mTOR pathway (26). T–DM1 acts as a cytotoxic HER2 therapy as well as an inhibitor of mitotic spindle signaling (27).

We first tested these 3 candidate drugs with HER2 exon 20YVMA mice in a first-line setting with 8 cohorts. After 2 weeks of treatment, mice in the mobocertinib and T–DM1 monotherapy groups had significant reduction in tumor volume compared with the vehicle group. That was not seen in the alisertib and sapanisertib monotherapy groups.
(Figure 5A). All 3 combination therapies significantly decreased the tumor volume compared with vehicle (Figure 5A).

After 6 weeks of treatment, mobocertinib and T–DM1 combination had the highest efficacy on HER2 exon 20^{YVMA} compared to mobocertinib or T–DM1 monotherapy and other combinational therapies with mobocertinib (Figure 5A-B). Importantly, mobocertinib and T–DM1 combinational treatment was able to prolong the progression–free survival of HER2 exon 20^{YVMA} mice (Figure 5C). Of note, mice treated with mobocertinib and T–DM1 combination showed sustained response for up to 24 weeks.

Next, in a mobocertinib acquired resistance setting, we investigated if monotherapy-resistant tumors showed similar responses to combinational therapies. Mice were treated with single-agent mobocertinib for 6–8 weeks until acquired resistance developed. Alisertib and T–DM1 were then added to mobocertinib. Although combination with alisertib showed stable disease, treatment with mobocertinib and T–DM1 showed significant shrinkage (Figures 5D-E). This effect was not seen in monotherapy with T–DM1–only sequential therapy (Figure 5D).

Taken together, this demonstrates that mobocertinib and T–DM1 combinational therapy was not only able to show robust efficacy for untreated HER2 exon 20^{YVMA} tumors and preventing acquired resistance, but could also provide promising efficacy in tumors that developed resistance.
M1 Macrophage Infiltration and CD4\(^+\) T-Cell Activation Contributed to the Synergic Effect of Mobocertinib and T–DM1 Combination

To elucidate the mechanisms involved in the enhanced efficacy of mobocertinib and T–DM1 combination, we performed bulk RNA sequencing and GSEA pathway analysis on the tumor nodules treated with the mobocertinib and T–DM1 combination after 3 days. Intriguingly, 6 immune-related pathways were enriched in the tumors treated with combination therapies, including “Interferon Alpha Response,” “Inflammatory Response,” “Interferon Gamma Response,” “IL2 Stat5 Signaling,” “TNF\(\alpha\) Signaling Via NF\(\kappa\)b,” and “IL-6 Jak Stat3 Signaling” (Figure 6A and Supplementary Table S2). Enrichment plots of immune-related enriched pathways are shown in Supplementary Figure S4A.

Using the CIBERSORT method (28), a well-established method for analyzing distinct immune-cell populations from RNA–Seq, tumor nodules from combination therapy with mobocertinib and T–DM1 showed a substantially stronger M1 macrophages transcriptional signature compared with that of mobocertinib monotherapy (Figure 6B). Considering the upregulation of immune–related pathways and the increasing trend of M1 macrophage in CIBERSORT analysis, we then used multi-parameter flow cytometry to directly characterize changes in immune cell populations during treatment with mobocertinib and T–DM1. Analysis of myeloid lineage showed significant increase in macrophage and monocytes (Figures 6C and 6D). In particular, M1 macrophages in
the combination group were increased compared with monotherapy (Figure 6E). In contrast, no changes were seen in neutrophil infiltration (Figure 6F). Analysis of lymphocytes showed no difference in quantities of T-cell or B-cell populations (Supplementary Figure S4B-E). However, combinational therapy increased activated CD4+ T-cells and decreased in naive CD4+ T-cells (Figures 6G-H).

Trastuzumab (antibody part of T–DM1) was proved to trigger antigen dependent cellular phagocytosis (ADCP) by interacting with Fcγ receptors on macrophages (29). Then we performed multi-immunofluorescence staining using DAPI (nucleus), TTF1 (tumor cells) and F4/80 (macrophage) in mobocertinib and T–DM1 treated mouse tumors. There were abundant macrophage infiltration along with triple positive cells, suggesting a role for macrophages in ADCP (Figure 6I).

Based on these findings, we suggested that mobocertinib contributes to the accumulation of HER2 on the cancer cell surface which binds to T–DM1, leading to both direct anti-cancer effect and infiltration of macrophages which function as ADCP. Meanwhile, M1 macrophages led to increased CD4+ T-cell activation. Thus, the immune tumor microenvironment following this mobocertinib and T–DM1 combinational treatment exhibits a more favorable anti-tumor phenotype.

The immune-profiling data indicated that macrophages play an essential role in tumor non-autonomous mechanism of mobocertinib and T–DM1 combinational therapy. To
further confirm this finding, we performed a macrophage depletion treatment experiment using the agent Clodrosome® (liposomal clodronate; Encapsula NanoSciences LLC, Brentwood, TN, USA), a liposome suspension encapsulated with clodronate, which selectively leads to macrophage apoptosis (30). Naive tumors showed significantly more positive area of F4/80 using IHC staining than Clodrosome treated ones, which indicated that Clodrosome successfully depleted macrophages (Supplementary Figure S4F). Triple combination treatment with Clodrosome, mobocertinib, and T–DM1 in GEMM HER2 exon 20YVMA–mutant mice abrogated the efficacy of mobocertinib and T–DM1 combination (Figure 6J).

In addition to mobocertinib and T-DM1, the therapeutic strategy to further enhance the function of macrophages as the third combination will be a future direction.

DISCUSSION
No targeted therapies are currently approved for HER2 exon 20 insertion mutation-driven NSCLC. Mobocertinib is a novel small-molecule TKI designed to selectively target EGFR and HER2 exon 20 insertion mutations and has been granted Breakthrough Therapy Designation by the US Food and Drug Administration for patients with metastatic EGFR exon 20 insertion–mutant NSCLC based on a phase1/2 clinical trial (43% confirmed objective response rate) (14). Considering the outstanding efficacy on EGFR exon 20 insertion–mutant lung cancer, it is necessary to explore the role of mobocertinib in HER2 exon 20 insertion–mutant lung cancer both in the preclinical and
clinical field (31). Preclinical data reported here represent a robust evaluation of mobocertinib in HER2 exon 20 insertion mutant lung adenocarcinoma. These data indicate that HER2 exon 20 insertion mutant cell lines, PDX and GEMMs can be robustly inhibited by mobocertinib. A limitation of our study is that we utilized one HER2 exon 20 mutant cell line (only one available) and PDX. It will be extremely important to further investigate in human tumor settings.

Several other TKIs have demonstrated pre-clinical activity and are also under clinical investigation. Afatinib, a pan-HER TKI, does not show the expected potential for disease control in patients (32). Tarloxotinib, a hypoxia-activated prodrug of a pan-HER TKI, exhibits antitumor activity in HER2 activating mutant NSCLC patient (33). DS-2087b, a selective inhibitor of EGFR/HER2 exon 20 insertions, demonstrated in vitro and in vivo inhibition in preclinical assays (34). Poziotinib demonstrated some efficacy in patients with HER2 mutations, but it was associated with high rates of WT EGFR-mediated toxicity (23,35). In our study, mobocertinib demonstrates robust anti-tumor activity in HER2 exon 20 insertion mutant pre-clinical models and manageable toxicity in patients with EGFR exon 20 insertion mutant lung adenocarcinoma in clinical trial (14).

Intriguingly, HER2 exon 20 insertion mutations respond differently to mobocertinib. In this study, we generated a new GEMM harboring HER2 exon 20^{G776>VC} mutation, which is a robust method to investigate the difference in response to mobocertinib among various type of insertions. Among the most frequent mutations, HER2 exon 20^{G776>VC}
tumors showed deeper and more sustained response than HER2 exon 20\textsuperscript{YVMA} tumors.

A recent published study suggested that YVMA insertion in the C-helix of the HER2 kinase domain generated a more rigid structure resulting to less amenable inhibition by TKI compounds (36).

In addition, further studies are needed to analyze the effect of co-mutations (such as \textit{TP53}) on response to mobocertinib in HER2 exon 20 insertion–mutant patients (37,38). From a clinical perspective, the next-generation sequencing results of both HER2 subtypes as well as co-mutation status should be examined.

Notably, we discovered the striking synergic effect of mobocertinib and T–DM1 on \textit{HER2} exon 20\textsuperscript{YVMA} lung cancer for both first–line and second–line settings when tumors developed acquired resistance. Even though the \textit{HER2} exon 20\textsuperscript{G776>VC} tumors showed sustained complete responses to mobocertinib for more than 16 weeks, acquired resistance inevitably occurred. It will be also essential to elucidate if the mobocertinib and T–DM1 combo can convert this resistance in \textit{HER2} exon 20\textsuperscript{G776>VC} tumors.

Previous studies indicate that lapatinib and poziotinib are capable of increasing HER2 expression on cancer cell surfaces through decreasing ubiquitination and then synergizing with the trastuzumab-conjugated cytotoxic drug to provide extra benefits (35,39). In our setting, \textit{HER2} mRNA was elevated after mobocertinib treatment, which suggested that it is likely to be through a transcriptional mechanism. However, whether
post-transcriptional mechanisms are involved is worthy of future investigation. Also, irreversible HER2 TKI neratinib was found to markedly increase T–DM1 internalization and enhance activity (40). Mobocertinib is an irreversible HER2 TKI and we found that mobocertinib is able to increase total HER2 expression. The combination with T–DM1 has synergic benefits on HER2 exon 20^{YVMA} tumors, which accounts for the majority of HER2 exon 20 insertion–mutant lung adenocarcinoma patients.

As little is known about how the immune microenvironment reacts to a small molecular TKI plus ADC, our study indicated that the infiltration of M1 macrophages and CD4^{+} T cell activation are the major drivers in mobocertinib and T–DM1 combinational therapy. This phenotype is consistent with previous findings that M1 macrophages were proved able to activate T cells (41-43). In our case, M1 macrophage is a critical component in the immune microenvironment upon mobocertinib and T-DM1 combinational treatment. The addition treatment to enhance macrophage’s function on top of mobocertinib and T-DM1 combination is a therapeutic direction to explore.

In conclusion, HER2 exon 20^{G776>VC} tumors responded to mobocertinib, while HER2 exon 20^{YVMA} tumors showed initial partial response but developed acquired resistance after continuous treatment. Using pathway analysis, we demonstrated that mobocertinib combined with T–DM1 showed potent efficacy in HER2 exon 20^{YVMA} untreated and resistant tumors. Furthermore, we investigated the mechanism involved in the synergic effect of mobocertinib and T–DM1 and elucidated that in addition to cancer cells’
autonomous effect, M1 macrophage infiltration and T cell activation may play vital parts. Above all, this paper provides a meaningful pre–clinical rationale for the development of mobocertinib clinical trials for patients with HER2 exon 20 insertion–mutant NSCLC.

Finally, given the prevalence of HER2 mutations across multiple cancer types, it will be vital to see if the combination of mobocertinib and HER2 antibody-drug conjugate (e.g. T–DM1 and the new emerging drug DS-8201) will remain effective on other cancer models. If so, this will support the clinical development of mobocertinib and HER2 ADC combinational treatments in patients with other HER2 mutation driven cancer types.
